(Received 25 June 2010; published 5 November 2010; corrected 12 April 2012)

We report the results of the first search for gravitational waves from compact binary coalescence using data from the Laser Interferometer Gravitational-Wave Observatory and Virgo detectors. Five months of data were collected during the Laser Interferometer Gravitational-Wave Observatory's S5 and Virgo's VSR1 science runs. The search focused on signals from binary mergers with a total mass between 2 and $35M_{\odot}$. No gravitational waves are identified. The cumulative 90%-confidence upper limits on the rate of compact binary coalescence are calculated for nonspinning binary neutron stars, black hole-neutron star systems, and binary black holes to be $8.7 \times 10^{-3} \text{ yr}^{-1} L_{10}^{-1}$, $2.2 \times 10^{-3} \text{ yr}^{-1} L_{10}^{-1}$, and $4.4 \times 10^{-4} \text{ yr}^{-1} L_{10}^{-1}$, respectively, where L_{10} is 10^{10} times the blue solar luminosity. These upper limits are compared with astrophysical expectations.

I. INTRODUCTION

The coalescence of a stellar mass compact binary is expected to produce gravitational waves detectable by ground-based interferometers. Binary neutron stars (BNS), binary black holes (BBH), and black hole-neutron star binaries (BHNS) can spiral together to produce signals in the frequency band where the Laser Interferometer Gravitational-Wave Observatory (LIGO) [1] and Virgo [2] detectors are most sensitive (40–1000 Hz).

LIGO was collecting data at the Hanford, Washington and Livingston, Louisiana sites as part of its fifth science run (S5) (4 November 2005—30 September 2007) when the first science run (VSR1) began at the Virgo detector in Cascina, Italy on 18 May 2007. During VSR1 the Virgo detector operated at reduced sensitivity since its commissioning was still incomplete. LIGO data collected before 18 May 2007 were analyzed separately and upper limits on the rate of gravitational waves from binary inspirals were reported in Refs. [3–5].

Here we describe the results of the first joint search for gravitational waves from compact binary coalescence with LIGO and Virgo data. This search covers gravitational waves from binaries with a total mass between $2M_{\odot}$ and $35M_{\odot}$ and a minimum component mass of $1M_{\odot}$. This analysis is based on the same methods as the S5 LIGO-only searches [4,5]. Since the analysis is considered integral in preparing for future joint searches in LIGO and Virgo data, further developments were performed to integrate Virgo into the pipeline, even though VSR1 data had limited sensitivity when compared with LIGO's S5 data. No gravitational-wave signal is identified and upper limits are calculated.

In Sec. II, we describe the data used in this analysis. The data reduction pipeline is explained in Sec. III and ends with a description of the detection statistic. The results and upper limits appear in Secs. IV and V. Details of a self-imposed blind injection challenge are given in the Appendix.

II. DATA QUALITY

The detectors are referred to as H1 (Hanford 4 km), H2 (Hanford 2 km), L1 (Livingston 4 km), and V1 (Virgo 3 km). Data from LIGO and Virgo are recorded in the same format, making it easier to run the LIGO pipeline on the additional detector. The relative sensitivities of these detectors can be assessed with horizon distance, the distance at which an optimally located, optimally oriented binary would produce triggers with a signal-to-noise-ratio (SNR) of 8 in the detector. When averaged over the duration of the search, the horizon distances for a 1.4 , $1.4M_{\odot}$ BNS system are approximately 37, 16, 32, and 8 Mpc for H1, H2, L1, and V1, respectively. See Fig. 1 for the horizon distance in each interferometer as a function of the total mass of the binary system.

It should be noted here that these curves were calculated using nonspinning post-Newtonian (PN) waveforms

FIG. 1 (color online). The average inspiral horizon distance over the run is shown as a function of the total mass of the binary system for each interferometer (H1, H2, L1, and V1). The error bars indicate variation over the duration of the run.

described in more detail in Sec. III. These waveforms do not include the part of the gravitational-wave signal corresponding to the merger of the two compact objects. The signal from this stage of coalescence is outside of the sensitive frequency band of the detectors for systems with total mass below $12M_{\odot}$, thus its omission is justified in the case of the lower mass binaries. For more massive systems its contribution to the SNR is no longer negligible [6]. Therefore, we anticipate an overall increase of horizon distance for systems with total mass above $12M_{\odot}$ and a shift to the right of the maxima of the curves in Fig. 1 if more realistic waveforms are used. For binary systems with total mass above $35M_{\odot}$, inclusion of the merger stage into the template waveform becomes essential. Although there are significant uncertainties associated with the last stage of coalescence, our search exploring the higher mass range (25 – $100M_{\odot}$) includes the merger stage in the template waveforms [7].

The detectors are very sensitive to their environments and fall out of science mode when disturbed, meaning that they are temporarily not recording science-quality data. Because the data streams from each detector are not continuous, different combinations of detectors may be taking data at any given time. As we describe in Sec. III A, we require time coincidence to identify possible gravitational waves and hence we only analyze the data when at least two detectors are operating. There are 11 combinations for what we define as *analysis time*: H1H2, H1L1, H1V1, H2L1, H2V1, L1V1, H1H2L1, H1H2V1, H1L1V1, H2L1V1, H1H2L1V1. Analysis time indicates that the listed detectors are collecting science-quality data. Because H1 and H2 are colocated, correlated noise leads to poor background estimates and hence H1H2 time was rejected.

A number of quality criteria were established before and during the run to reject times when the data are unreliable, either due to instrumental problems or external factors. See Appendix A of Ref. [4] for a more thorough description of

the *veto categories* we use. We do not analyze data rejected by Category 1 vetoes because it indicates severe problems. Category 2 vetoes remove artifacts with a well-understood origin and coupling. Category 3 vetoes are based on statistical correlations, and Category 4 vetoes are the least serious and only used in the candidate follow up procedure. We make our candidate event list and perform the upper limit calculation with data that passes Category 1 + 2 + 3 vetoes. We also look for loud candidates with significantly low false alarm probability that occur during times rejected by Category 3 (but that pass Category 1 + 2 vetoes). When only Category 1 + 2 vetoes are applied, 115.2 days of data are analyzed; when Category 1 + 2 + 3 vetoes are applied, 101.1 days of data are analyzed. Our two most sensitive detectors (H1 and L1) were simultaneously running during 68% of this time.

III. THE DATA ANALYSIS PIPELINE

The data processing is performed in a similar manner to the S5 LIGO-only analyses [4,5], although the addition of Virgo to the pipeline led to enhancements in the ranking method for candidates. Because of long-term variations in detector performance, data are analyzed in one-month blocks of time in order to obtain more accurate background estimates. There are four approximately 30-day blocks and one 19-day block and each time period is analyzed with an identical pipeline. The results of these five periods are combined with previous analyses into one set of upper limit statements.

A. Overview of Pipeline

As described in the LIGO-only searches [4], the analysis begins with four separate data streams, one from each detector. We construct template banks [8] of nonspinning PN waveforms [9–19]. The template waveforms were calculated in the frequency domain using the stationary-phase approximation [10,17,18] to Newtonian order in amplitude and second PN order in phase. The waveforms were extended up to the Schwarzschild innermost stable circular orbit. These templates cover a range of binary mass combinations, (m_1, m_2) . The single-detector data are match filtered with the templates and the resulting triggers pass to the next pipeline stage if they exceed an SNR of 5.5 [20]. Because the background does not follow a Gaussian distribution, the false alarm rate is quite high in single-detector data. To reject noise artifacts, we use signal-based vetoes [21,22], including a χ^2 test [23], and require triggers from different detectors to be coincident in time and mass parameters [24]. We define *event type* as the combination of detectors contributing to a given coincident trigger. A double coincidence trigger can occur during double, triple, or quadruple analysis time, while a quadruple coincidence can only occur during quadruple analysis time. We apply consistency tests on the coincident triggers. For example, since H1 is about twice as sensitive as H2, any coincidence

that includes an H2 trigger, but not an H1 trigger when H1 was collecting data, is rejected. The remaining triggers are ranked based on an estimate of their likelihood of being a true signal or background. Any candidate events that stand out significantly above the background are followed up with a more detailed study of the triggers and detector conditions at the time of the event [25].

The background for the search is estimated by time shifting the data from the different detectors. The time shifts are larger than the light-travel time between any pair of detectors, therefore any observed coincidences in this data are accidental. The L1 and V1 data streams are shifted in increments of 5 and 15 seconds, respectively, while the H1 and H2 data streams are held fixed with respect to each other. This is because H1 and H2 are colocated, and noise from environmental disturbances is correlated in these interferometers. For this same reason, the background for H1H2 triggers can not be reliably estimated. H1H2 triggers are excluded from the calculation of the upper limit, but the loudest are followed up to ensure exceptional candidates are not missed.

B. Parameter choices and tuning

Many analysis parameters are determined at the onset of the analysis based on known properties of the individual detectors. LIGO data is analyzed above 40 Hz, and templates for the LIGO detectors cover a region with total masses between $2M_\odot$ and $35M_\odot$. Virgo data quality information is best in the high frequency region, therefore the low frequency cutoff is set to 60 Hz for Virgo data. Consequently, the Virgo template bank is constructed to cover only the BNS mass region, with a minimum total mass of $2M_\odot$ and maximum chirp mass of $2.612M_\odot$ [where chirp mass is $\mathcal{M}_c = ((m_1 m_2)^3 / (m_1 + m_2))^{1/5}$ and $m_1 = m_2 = 3M_\odot$].

In addition to the blind hardware injection described below in Sec. IV B and the Appendix, we validate our pipeline using numerous nonblind hardware injections, which we have found to be recovered as expected. We also perform large numbers of software injections in order to tune our search algorithms and measure their efficiency in detecting signals.

When optimally tuned, veto cuts and consistency tests remove a significant number of background triggers while having minimal effect on the detection efficiency for simulated signals. With the addition of a fourth detector, the tuning was revisited. In the process of tuning we set the appropriate parameters for Virgo and verified that the corresponding parameters for the LIGO detectors did not need to be changed from those used in S5 LIGO-only analyses.

C. Detection Statistic

In Refs. [4,5], coincident triggers that survived all veto cuts and consistency tests [21] are ranked according to

their combined effective SNR, ρ_c , first used as a detection statistic in the analysis of data from the S3 and S4 LIGO science runs [3]. The combined effective SNR statistic is based on the standard SNR, but it incorporates the value of the χ^2 test into its definition [23]. Its effect is to assign a lower detection statistic to those coincident triggers that have high values of the χ^2 , indicating that they are less consistent with the expected gravitational waveform. Further details concerning construction of the combined effective SNR can be found in Appendix C of Ref. [4].

As observed in previous LIGO analyses, both the total rate of triggers and their distribution over effective SNR vary strongly with total mass. Variation also exists for each event type across different analysis times. Additionally, one should consider significant differences in detector sensitivities, for example, the H2 and V1 detectors are much less sensitive than either H1 or L1. As a result, some analysis times are more efficient in detecting gravitational waves than others. Within a specific analysis time, certain event types are more likely to be associated with a gravitational-wave event. Hence we specifically distinguish all of the possible combinations of event type and analysis time.

In order to account for variation in background rates and differences in the sensitivity of the detectors, we implemented the following post-processing algorithm. First, coincident triggers that survive the main pipeline are clustered such that only the trigger with the highest combined effective SNR within a 10 s window is kept. Then clustered triggers are subdivided into categories by analysis time, event type, and mass. Based on regions of similar background behavior, we define three mass bins: $0.87 \leq \mathcal{M}_c/M_\odot < 3.48$, $3.48 \leq \mathcal{M}_c/M_\odot < 7.4$, and $7.4 \leq \mathcal{M}_c/M_\odot < 15.24$. These correspond to equal mass binaries with total masses of $2M_\odot$ – $8M_\odot$, $8M_\odot$ – $17M_\odot$, and $17M_\odot$ – $35M_\odot$. For every trigger in each category, using our estimate of the background (time-shifted data), we calculate the rate $R_0(\rho_c, m, \alpha, \beta)$ of background triggers with combined effective SNR greater than or equal to that of the trigger. The mass bin is indicated by m , while α and β are the event type and analysis time. Next, we introduce efficiency factors that estimate the probability of detecting a signal with a given combination of detectors in a specific analysis time. Virgo only has templates covering the BNS mass space, therefore in the calculation of the efficiency factors we use a population of simulated BNS gravitational-wave signals injected into the data. This procedure accounts for most of the effects introduced by variations in the detector sensitivities. Because the population of simulated signals is distributed uniformly in inverse distance, a reweighting is necessary. The efficiency factors are defined as

$$\epsilon(\alpha, \beta) = \frac{\sum_{\text{found}} D_{\text{inj}}^3}{\sum_{\text{all}} D_{\text{inj}}^3}. \quad (1)$$

The numerator is a sum of all injections found for that particular α and β . The denominator sums over all injected signals during a particular analysis time, β . D_{inj} is the injected distance to the binary.

Finally we define the detection (or ranking) statistic, L , for the search to be

$$L(\rho_c, m, \alpha, \beta) = \ln \left[\frac{\epsilon(\alpha, \beta)}{R_0(\rho_c, m, \alpha, \beta)} \right]. \quad (2)$$

For gravitational-wave detection, a candidate is expected to have an L value significantly larger than the background. We have tested this algorithm on simulated signals and find that it results in a substantial increase in overall efficiency of the search.

IV. RESULTS

A list of the loudest events is generated after Category 1 + 2 + 3 vetoes are applied. However, in order not to unnecessarily dismiss a possible detection, we also look for any loud candidates that might have occurred when a Category 3 veto was active (times that pass only Category 1 + 2 vetoes). Candidates from these times may still stand above the background, but must be closely studied to differentiate them from the elevated background noise that the Category 3 veto is intended to remove.

A. Results from times that pass category 1 + 2 + 3 vetoes

After Category 1 + 2 + 3 vetoes are applied, we find no events with a detection statistic significantly larger than the background estimation. In Fig. 2, the data are overlaid on the background. The inverse false alarm rate is calculated with detection statistic L defined by Eq. (2). The loudest trigger in the five-month span is an H1L1 coincidence from H1H2L1V1 time with a false alarm rate of 19 per yr. As 0.28 yr was searched, this is consistent with the background expectation.

However, as seen in Fig. 2, there are fewer foreground triggers than the mean background. While the foreground lies within the $2N^{1/2}$ uncertainties, we performed a series of tests to exclude an error in the analysis or a bias in the way the foreground was handled with respect to the background. We ran the analysis on simulated Gaussian noise data. No deficit of foreground triggers in the tail of the distribution was found, which suggests that there is no problem in the analysis procedure or codes. We studied how the data quality and vetoes were applied in the analysis and found no error. We also changed the segmentation of the data and observed that the foreground events were shifted within the expectation for random fluctuations. Thus, we conclude that the results are consistent with a fluctuation of the foreground compared to the background.

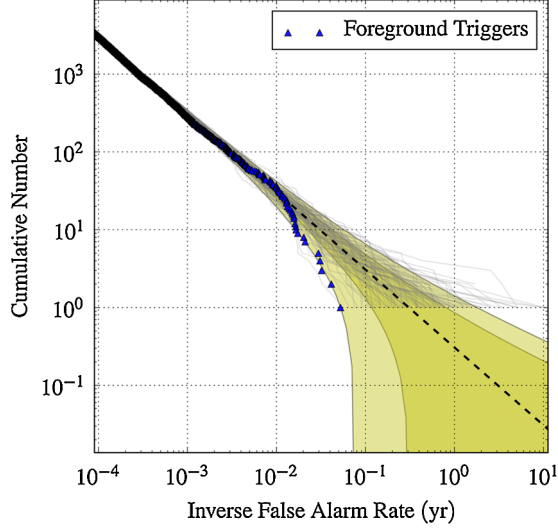

FIG. 2 (color online). A cumulative histogram of the inverse false alarm rate using L as the detection statistic. The data are represented by the triangles and each gray line represents a background trial made from time shifting the data against itself. The darker and lighter shaded regions denote $N^{1/2}$ and $2N^{1/2}$ errors, respectively. The data combine triggers from all five LIGO-Virgo months when Category 1 + 2 + 3 vetoes are applied.

B. Results from times that do not pass category 3 vetoes

An event list was generated for times when Category 3 vetoes were active, meaning that the events were only able to survive the Category 1 + 2 vetoes. Only one event is inconsistent with the estimated background. That sole significant candidate, an H1H2L1 triple coincidence, is a hardware injection, part of a *blind injection challenge*. During four months of S5/VSR1, the LIGO and Virgo Collaborations agreed that simulated signals would be inserted into the LIGO-only data without the search groups knowing the time or number of injections and their parameters. This was an exercise to test the effectiveness of the search procedures and all blind injection triggers are removed from the results presented in this publication.

This sole candidate corresponds to a blind injection signal that was injected into the LIGO data during a time of high seismic activity at low frequencies at the LIGO Livingston Observatory. A Category 3 veto rejected this time period and hence this blind injection signal was not identified in the Category 1 + 2 + 3 event list. Unfortunately, the parameters of the blind injection challenge were revealed after the Category 1 + 2 + 3 event list was produced, but before we looked for significant candidates that might have been removed by Category 3 vetoes. Hence, the follow up procedure for significant candidates was not exercised until after the injection parameters were known. Detailed investigations related to the blind injection challenge are described in the Appendix.

C. Results for H1H2 double coincidences

Although we do not have reliable estimates of the detection statistic for H1H2 events, we did look for interesting H1H2 candidates and found one that passed Category 1 + 2 + 3 vetoes. It corresponds to the same blind injection mentioned earlier. When the candidate was vetoed in L1, it became an H1H2 double candidate (see the Appendix). No other interesting H1H2 candidates are identified.

V. UPPER LIMITS

Other than the blind injection candidate, no significant candidates are identified after Category 1 + 2 + 3 vetoes are applied or when Category 3 vetoes are disregarded. We calculate upper limits on the rate of compact binary coalescence for the following astrophysical objects after Category 1 + 2 + 3 vetoes are applied: BNS [$m_1 = m_2 = (1.35 \pm 0.04)M_\odot$], BHNS [$m_1 = (5 \pm 1)M_\odot$, $m_2 = (1.35 \pm 0.04)M_\odot$], and BBH [$m_1 = m_2 = (5 \pm 1)M_\odot$]. We also present upper limits as a function of the total mass of the binary and as a function of the black hole mass for BHNS binaries.

The upper limits are reported for both nonspinning and spinning objects in Table I. Only nonspinning templates are used in this search, so there is an additional loss of efficiency associated with spinning waveforms that leads to slightly less-constrained upper limits in the spinning case. The results are reported as a rate in units of number per L_{10} per yr, where L_{10} is 10^{10} times the blue solar luminosity, which is expected to be proportional to the binary coalescence rate [26]. The horizon distance listed in Table I is approximated for the H1 or L1 detector and is a good estimate of the sensitivity of the search.

We calculate our upper limits using the loudest event from the search, as described in Ref. [27]. In this method, the posterior distribution for the rate depends on two quantities, \mathcal{C}_L and Λ , that are functions of the loudness parameter, x . In our experiment, x is the inverse false alarm rate of the loudest observed event according to the detection statistic in Eq. (2). Λ is a measure of the likelihood of detecting a single event with loudness parameter, x , versus such an event occurring in the experimental background. \mathcal{C}_L is the cumulative luminosity of sources that produce signals that are louder than x . Assuming a uniform prior, the posterior distribution for the rate of coalescence is given by

$$p(\mu|\mathcal{C}_L, T, \Lambda) = \frac{\mathcal{C}_L T}{1 + \Lambda} (1 + \mu \mathcal{C}_L T \Lambda) e^{-\mu \mathcal{C}_L T}, \quad (3)$$

where μ is the rate and T is the analyzed time. In general, Λ is given by [27]

$$\Lambda(x) = \left(-\frac{1}{\mathcal{C}_L} \frac{d\mathcal{C}_L}{dx} \right) \left(\frac{1}{P_0} \frac{dP_0}{dx} \right)^{-1}, \quad (4)$$

TABLE I. Summary of results. The horizon distance is averaged over the time of the search. The cumulative luminosity combines the detection efficiency with the galaxy catalog luminosity. Here, the value is the time-weighted average of the cumulative luminosity for each month. Many uncertainties are included in the calculation of the upper limit and they are summarized over all months. The effects of spin on BNS systems are negligible and not reported here.

	BNS	BHNS	BBH
Component Masses (M_{\odot})	1.35/1.35	5.0/1.35	5.0/5.0
Horizon Distance (Mpc)	~ 30	~ 50	~ 90
Cumulative Luminosity (L_{10})	370	1600	8300
Calibration Error	13%	14%	14%
Monte Carlo Error	17%	17%	18%
Waveform Error	19%	18%	16%
Galaxy Distance Error	-16%	-13%	-13%
Galaxy Magnitude Error	29%	30%	31%
Nonspinning Upper Limit ($\text{yr}^{-1} L_{10}^{-1}$)	8.7×10^{-3}	2.2×10^{-3}	4.4×10^{-4}
Spinning Upper Limit ($\text{yr}^{-1} L_{10}^{-1}$)	...	2.7×10^{-3}	5.3×10^{-4}

where P_0 is the probability of obtaining zero background events louder than x for the given search and observation time.

The cumulative luminosity measures how many potential sources we can detect with this search, based on the blue light luminosity of galaxies. To find the cumulative luminosity, we take the product of the detection efficiency, calculated as a function of mass and distance, and the luminosity from galaxies in the catalog [26] and integrate over distance. We marginalize over our uncertainties when calculating the cumulative luminosity using the values given in Table I. These include detector calibration, Monte Carlo error, distances and luminosities given in the galaxy catalog and inaccuracies in the template waveforms [28]. The results from all five months and the prior S5 results [4,5] are combined by taking the product of their posterior distributions calculated with uniform priors as in Eq. (3). Figure 3 shows the probability distribution from the combined data for the rate of BNS coalescence.

When spin is neglected and the priors from previous LIGO searches are used, the upper limits on the rate of compact binary coalescence are

$$\mathcal{R}_{90\%,\text{BNS}} = 8.7 \times 10^{-3} \text{ yr}^{-1} L_{10}^{-1}, \quad (5)$$

$$\mathcal{R}_{90\%,\text{BHNS}} = 2.2 \times 10^{-3} \text{ yr}^{-1} L_{10}^{-1}, \quad (6)$$

$$\mathcal{R}_{90\%,\text{BBH}} = 4.4 \times 10^{-4} \text{ yr}^{-1} L_{10}^{-1}, \quad (7)$$

which are consistent with upper limit estimates based solely on the sensitivity and observation time of the detectors [26].

Astrophysical observations of neutron stars indicate that their spins will be too small to have a significant effect on binary neutron star waveforms observable by LIGO [29,30], hence we do not report upper limits for spinning BNS systems. However, we do consider spin effects on the upper limit for BHNS and BBH systems. The black hole

spin, S , must be less than Gm^2/c . Following an identical procedure to that described in [4], we sample from a uniform distribution of possible spin values in order to simulate the effect of spin on our ability to detect the binary system. With black hole spin included, the upper limits on the rate of compact binary coalescence are

$$\mathcal{R}_{90\%,\text{BHNS}} = 2.7 \times 10^{-3} \text{ yr}^{-1} L_{10}^{-1}, \quad (8)$$

$$\mathcal{R}_{90\%,\text{BBH}} = 5.3 \times 10^{-4} \text{ yr}^{-1} L_{10}^{-1}. \quad (9)$$

We also produce two sets of upper limits as a function of mass. The BBH upper limit shown in Fig. 4 assumes a

FIG. 3 (color online). The posterior probability distribution for the rate of nonspinning BNS coalescence. The results of all previous LIGO searches are included in the plot as the prior, labeled as S5 LIGO-only Months 0–18. Each of the five LIGO-Virgo month results was combined with the prior to obtain the combined posterior, shown as the solid black line.

FIG. 4. The 90% rate upper limits as a function of mass. The upper panel gives the upper limit on the rate of coalescence from BBH systems as a function of the total mass of the system. The lower panel gives the BHNS upper limit as a function of black hole mass, assuming a fixed neutron star mass of $1.35M_{\odot}$.

uniform distribution of the component mass. The BHNS upper limit is shown as a function of black hole mass, assuming a fixed neutron star mass of $1.35M_{\odot}$.

VI. CONCLUSIONS

We searched for gravitational waves from compact binary coalescence in the mass region $2M_{\odot}$ to $35M_{\odot}$. Over 101 days of coincident data were collected during the end of the LIGO S5 and Virgo VSR1 runs, making this the first joint search for gravitational waves from compact binaries with LIGO and Virgo data. The LIGO data analysis pipeline was augmented to handle the extra complexity of four detectors and a larger number of coincidence categories. Although no gravitational-wave candidates are identified, upper limits on rates of binary coalescence are established. The upper limits improve when combined with the previous LIGO-only results. These upper limits are still more than an order of magnitude larger than optimistic astrophysical expectations [31]. Hardware upgrades performed upon the completion of the S5 and VSR1 science runs should yield better sensitivity in future searches. With the advent of three-site analyses, sky localization techniques are being developed to reconstruct the direction of any gravitational-wave sources detected in the future.

Sloan Foundation. This document has been assigned LIGO Laboratory document number P0900305-v6.

APPENDIX: BLIND INJECTION CHALLENGE

During the blind injection challenge, simulated signals were inserted into the LIGO-only data without the search groups knowing the time or number of injections and their parameters. Two blind injections occurred in the data described in this paper. The first simulated a burst of gravitational waves. The injected signal was the sum of two Gaussian modulated sinusoids with a linearly time-varying frequency. The root-square-sum amplitude h_{rss} for the signal was 1.0×10^{-21} at the Earth. The dominant component was at 58 Hz and the duration was about 12 ms. This injection was not a target of this analysis and was not identified as a significant candidate. However, see Ref. [32] about the significance of this injection in the Collaboration's burst search.

The second blind injection was the simulated binary inspiral signal referred to in Sec. IV. The waveform simulated a binary system with masses 1.1 and $5.1M_{\odot}$, with small spins 0.19 and 0.06 , respectively, in dimensionless units of the spin parameter $\hat{a} = (cS)/(Gm^2)$, at effective distance of 34.6 Mpc for Hanford and 42.2 Mpc for Livingston. The candidate identified in H1, H2, and L1 has nonspinning templates with masses $(1.0, 5.9)$, $(1.0, 5.7)$, $(1.1, 5.6) M_{\odot}$, and effective distances $(43.6, 33.2, \text{ and } 42.2)$ Mpc, respectively. Given the parameters of the signal, the absence of a Virgo trigger in the coincidence does not cast any doubt on the validity of the candidate. The loudest coincidence in the time slide background had a false alarm rate of 1 per 14 yr. As this candidate was louder

than that, 1 per 14 yr is only a bound on its significance level.

Since a candidate was identified coincident with this injection, we conducted an extensive follow up study [25]. As part of the study, the SNR time series, χ^2 time series, and time-frequency spectrograms at the time of the candidate were inspected. We also studied environmental influences on the detectors since this candidate was vetoed by a Category 3 data quality flag produced for high seismic noise at low frequencies at the Livingston Observatory.

The 30–40 min period of high seismic activity was due to earthquakes near Sumatra, which produced large ground motion at Livingston (but not Hanford) at frequencies between 0.03 and 0.1 Hz. There was a higher rate of accidental coincidences in the time-slid data when using L1 triggers produced a few minutes after the time of the candidate. These accidental coincidences were coincident with peaks in seismic activity and excess power in the L1

gravitational-wave channel. These accidental coincidences were HIL1 (double) coincidences, less significant than the triple coincidence candidate seen at the time of the blind injection. No triple accidental coincidences were observed within that active seismic time. The time series of the gravitational-wave channel at the time of the candidate does not bear any resemblance to those at the times of the double coincidences correlated to seismic noise.

The candidate passed all tests related to the pipeline and the statistical analysis. The presence of the seismic data quality flag in the time around this candidate does not substantially downgrade its significance. Had there not been a blind injection at the time of this candidate, it would have been recognized as having an interesting level of statistical significance, and we would likely have pursued this candidate by dismissing seismic activity as its cause. We are developing improved methods to better estimate the significance of such detection candidates.
