16 **ABSTRACT**

17 Membrane clogging and biofilm formation are the most serious problems during water
18 filtration. Silver nanoparticle (Ag_{nano}) coatings on filtration membranes can prevent bacterial
19 adhesion and the initiation of biofilm formation. In this study, Ag_{nano} are immobilized via direct
20 reduction on porous zirconia capillary membranes to generate a nanocomposite material
21 combining the advantages of ceramics being chemical, thermal and mechanical stable with
22 nanosilver, an efficient broadband bactericide for water decontamination. The filtration of
23 bacterial suspensions of the fecal contaminant *E. coli* reveals highly efficient bacterial
24 retention capacities of the capillaries of 8 log reduction values, fulfilling the requirements on
25 safe drinking water according to the U.S. Environmental Protection Agency. Maximum
26 bacterial loading capacities of the capillary membranes are determined to be 3×10^9 bacterial
27 cells/750 mm² capillary surface until back flushing is recommendable. The immobilized Ag_{nano}
28 remain accessible and exhibit strong bactericidal properties by killing retained bacteria up to
29 maximum bacterial loads of 6×10^8 bacterial cells/750 mm² capillary surface and the
30 regenerated membranes regain filtration efficiencies of 95-100 %. Silver release is moderate
31 as only 0.8 % of the initial silver loading is leached during a three-day filtration experiment
32 leading to average silver contaminant levels of 100 µg/L.

40 1. INTRODUCTION

41 Water purification technologies play an important role in reducing the risk of the
42 dissemination of waterborne diseases or epidemic outbreaks that are caused by pathogenic
43 microorganisms and viruses. Bacteria such as pathogenic serovars of *Salmonella* and *Vibrio*
44 *cholerae* are responsible for severe diseases such as typhoid fever and cholera, and *E. coli*
45 serves as an important indicator organism for fecal contaminations. Today, more than
46 250 serotypes of *E. coli* are known ranging from harmless gut commensals to severe
47 pathogens [1], such as the virulent enterotoxigenic (ETEC), enteropathogenic (EPEC), and
48 enterohaemorrhagic (EHEC) *E. coli*. Furthermore, viral infections can be spread via drinking
49 water contaminations and highly infectious diseases are for example hepatitis A, poliomyelitis
50 caused by the poliovirus or the severe acute respiratory syndrome (SARS) which is caused
51 by the coronavirus.

52 Because bacterial contaminations in drinking water are nowadays the main reason for most
53 of the upcoming diseases [2], the removal and inactivation of pathogenic coliforms and other
54 microorganisms is therefore a field of great interest for both, industries and local authorities.
55 These institutions are obliged to fulfill the requirements on water containing 0 fecal and total
56 coliform counts in 100 mL of water intended for drinking [3]. Hence, small-sized water
57 filtration systems that can be easily transported and provide sufficient amounts of purified
58 water are of global interest [4].

59 Different filtration materials have been described for the use in water purification, such as
60 polymeric materials like cellulose acetate (CA) [5], polysulfone (PS) [6], polyacrylonitrile
61 (PAN) [7] or polyvinylidene fluoride (PVDF) [8], while polyethersulfone (PES) is the most
62 commonly used material for membrane applications [9]. In contrast to polymeric filter
63 materials, ceramics feature outstanding positive properties because they are usually bio-
64 inert, do not undergo swelling, are chemically and thermally stable, and withstand high
65 mechanical stress enabling the cleaning and reuse of the filter after heat or acid/base

66 treatment for decontamination [10, 11]. These excellent properties result in an increased
67 membrane service life compensating the higher costs of ceramics in comparison to polymeric
68 materials.

69 The most common problem during bacteria filtration is the formation of biofilms on the
70 membrane surface leading to pore clogging and consequently, a reduction of the filter
71 performance is given. These clustered bacterial communities are attached to the membrane
72 surface and protect themselves against environmental influences. Bacteria produce
73 extracellular polymeric substances (EPS) to form complex macroscopic structures that
74 increase their resistance against e.g. toxic chemicals and antimicrobial agents. The removal
75 of biofilms from the membrane surface is challenging and result in both cost- and time-
76 intensive membrane regeneration procedures. Therefore, the reduction of the initial physical
77 attraction of bacteria to the membrane surface, which can be attributed to a reversible
78 attachment [1], plays a key role in inhibiting the formation of biofilms and several antibacterial
79 surfaces have already been proposed [12, 13]. Especially, immobilized nanosilver can act as
80 an efficient antibacterial agent by killing retained bacteria directly on the membrane surface.

81 The decoration of filtration membranes with nanomaterials [14] have come into spotlight for
82 water decontamination, catalysis and environmental remediation exploiting their unique
83 surface chemical activities. Though the use of silver as an antimicrobial agent is known for
84 about 7000 years [15], upcoming with the urgent need to eradicate antibiotic-resistant
85 bacteria and with new insights into the mechanism of action [16], the use of silver has
86 regained an emerged interest along with new interesting fields of applications [17]. Silver
87 displays a broad antibacterial spectrum against Gram-positive and -negative bacteria [18]
88 and nanosilver is one of the safest and mildest antibacterial agents for mammalian cells [19].

89 In recent years, silver nanoparticles (Ag_{nano}) have been embedded into various materials to
90 generate antibacterial composites [20-23] and especially polymeric nanocomposite
91 membranes are produced for water filtration purposes [6, 14, 24-27], since nanoparticles

92 feature advantages in comparison to bulk silver: i) very small amounts of silver are needed
93 due to the high specific surface area of silver nanoparticles, ii) when compared to silver ions,
94 the bactericidal effect of Ag_{nano} is long-lasting because zerovalent (metallic) Ag_{nano} are not
95 inactivated by complexation and precipitation [28] iii) a controllable release of Ag⁺-ions from
96 the particles [29] compose them a cost-effective material for surface coatings. Most of the
97 studies investigated the antibacterial properties of the nanocomposite membranes by
98 describing the effect of the physical contact between silver nanoparticles and bacterial cells,
99 but experiments were not performed under filtration conditions with special focus on
100 antibacterial efficiency and silver leaching [27].

101 In our study, we present an advanced water filtration system based on ceramic capillary
102 membranes which are subsequently doped with Ag_{nano}. Using zirconia as membrane material
103 and Ag_{nano} as bactericidal coating, we combine a promising filtration material exhibiting high
104 fracture toughness and bending strength with a highly effective antibacterial agent. Pore
105 sizes of the capillary membrane of less than 0.2 μm and high open porosities of 51 % enable
106 the retention of bacterial cells during filtration [30]. Generated by direct reduction of silver
107 nitrate on the membrane surface, immobilized Ag_{nano} display a bactericidal surface that kills
108 filtrated bacteria directly on the membrane surface. Filtration experiments were performed by
109 applying intracapillary feeding with bacterial suspensions and bacterial retention after
110 different filtration times was determined using microbiological methods. The viability of
111 retained bacteria was analyzed to evaluate the bactericidal action of immobilized Ag_{nano} and
112 silver leaching during filtration was determined to consider eco-toxicological requirements.

113

114

115

116

117 2. MATERIALS AND METHODS

118 *2.1 Preparation of Ag_{nano}-doped zirconia capillaries*

119 Zirconia capillary membranes were fabricated by extrusion and sintered at 1050°C for 2 h as
120 described in our previous study [30]. As shown in Fig. 1, Ag_{nano} were immobilized on the
121 membrane surface by a two-step immersion procedure according to the Creighton method
122 [31] by direct reduction of silver ions on the surface of the capillaries. Capillaries featured an
123 outer diameter (D_o) of 1.48 ± 0.01 mm, an inner diameter (D_i) of 0.90 ± 0.01 mm and an
124 average wall thickness of 0.29 mm ± 0.01 mm. For all further tests, capillary pieces of 25 mm
125 length were used which is in accordance with a weight of 82.9 ± 0.7 mg and a geometric
126 surface area of 189 mm², except for the filtration experiment where 100 mm capillaries were
127 applied (geometric surface area of 750 mm²).

128 For the immobilization of Ag_{nano} one sintered capillary with a length of 25 mm was immersed
129 in 2 mL silver nitrate (AgNO₃) solution (Sigma Aldrich, Germany, Product number 209139)
130 with varying concentrations from 2.5 to 10 mM at 25°C and shaken at 1000 rpm for 5 min (pH
131 was not adjusted). For the reduction of the immobilized silver ions, capillaries were
132 subsequently immersed in 2 mL sodium borohydrate (NaBH₄) (Sigma Aldrich, Germany,
133 Product number 209139) for further 5 min. The reduction of the pre-immobilized silver ions
134 was performed using a constant concentration of 2 mM NaBH₄. Prior to use, the NaBH₄
135 solution was stirred for 30 min at 25°C followed by a cooling step to 4°C without adjusting the
136 pH. The number of immersion steps was varied between 1, 3, 5 and 10. Afterwards, the
137 capillaries were washed twice in 15 mL of ddH₂O under shaking at 1000 rpm for 5 min to
138 remove unbound and weakly bound silver and finally dried at 70°C for 30 min.

139

140 **Fig. 1 Synthesis of zirconia capillaries by extrusion and immobilization of Ag_{nano} by reduction**
 141 **of AgNO₃ using NaBH₄**

142 Zirconia capillaries with an outer diameter (D₀) of 1.48 ± 0.01 mm, an inner diameter (D_i) of
 143 0.90 ± 0.01 mm and an average wall thickness of 0.29 mm ± 0.01 mm were fabricated by extrusion.
 144 The extruded capillaries were dried at room temperature for 2 days and the obtained green parts were
 145 sintered at 1050°C for 2 h. Silver ions were directly reduced on the surface of the capillary membranes
 146 by immersion in AgNO₃ solution with varied concentrations and subsequently reduced in NaBH₄ at
 147 a constant concentration of 2 mM. This two-step immersion procedure was repeated 1-5 times to obtain
 148 adequate silver loading capacities.

149

150 **2.2 Silver loading capacities of Ag_{nano}-capillaries**

151 Silver loading capacities were determined by three different methods: i) manual counting of
 152 immobilized Ag_{nano}, ii) image analysis using an image processing algorithm and iii) atomic
 153 absorption spectroscopy (AAS).

154 Scanning electron microscopy (SEM) micrographs of untreated and Ag_{nano}-capillaries were
 155 taken with a SEM Supra 40 (Carl Zeiss, Germany) operated at 2 kV. The chemical
 156 composition of both the membrane material and immobilized Ag_{nano} was recorded using an
 157 energy-dispersive X-ray spectroscopy (EDX) detector (BrukerXFlash 6|30, Bruker Nano
 158 GmbH, Germany). The number of immobilized Ag_{nano} on the membrane surface was
 159 determined by manual counting using three different SEM micrographs for each membrane
 160 sample and four randomly chosen micrograph sections covering an area of 1 μm².

161 Additionally, the micrographs were analyzed using an image processing algorithm called
162 "Silver-Particle Analyzer". The algorithm was developed in C# using Visual Studio 2012 with
163 .NET 3.5 Framework and AForge.NET 1.7.0 Framework. The program used the
164 characteristic gray-value distribution of the Ag_{nano} on the SEM micrographs. The analyses
165 were carried out by screening the SEM images with a so-called top-hat filter. The top-hat
166 filter is applied at a fixed size of 7x7 pixels which can be attributed to the size range of the
167 Ag_{nano}. To consider exclusively the Ag_{nano} and no parts of the porous substrate, the contrast
168 was increased and a threshold value for bright image segments was applied. The algorithm
169 was used to quantify the percentage of Ag_{nano}-covered capillary surface and the total surface
170 of bioactive silver based on the assumption that all Ag_{nano} were spherical. Results were
171 compared with total silver loadings obtained from AAS analysis.

172 AAS measurements were performed to determine the total amount of immobilized Ag_{nano} on
173 the surface of the capillaries. To quantify the silver loading, one 100 mm Ag_{nano}-capillary was
174 acidified in 10% HNO₃ at 25°C overnight. Due to applied acidic conditions, a complete
175 release of the immobilized silver from the capillaries was enforced. An aliquot of 100 µL of
176 the solution was stored at 4°C until AAS measurements were performed (measurements
177 were performed in triplicate using three individual capillaries). The silver loading was
178 quantified by graphite furnace AAS using an Unicam 989 QZ AA Spectrometer with GF90
179 plus furnace and FS90 plus autosampler (Unicam, Cambridge, UK) after *aqua regia*
180 digestion. The digestion was carried out by adding 80 µL of concentrated HCl (37 %, p.a.
181 VWR, Germany) and 20 µL of concentrated HNO₃ (≥65 %, puriss p.a., Sigma-Aldrich,
182 Germany) to the samples. After short mixing and centrifugation, the open samples were
183 tempered at 56 °C overnight. The dry residue was dissolved in 1 mL diluted *aqua regia*
184 (containing 10 % HNO₃ and 19 % HCl). Subsequently, the samples were measured after
185 further dilution to be in the working range of the AAS (0.5 – 20 µg Ag L⁻¹).

186

187 **2.3 Tests on antibacterial properties and filtration efficiencies of Ag_{nano}-capillaries**

188 For all tests, bacterial suspensions of *E. coli* (Deutsche Sammlung von Mikroorganismen und
189 Zellkulturen, Germany, DSMZ No. 1077) were prepared by inoculating a pre-culture in 70 mL
190 of lysogeny broth (LB) (Sigma Aldrich Germany, No. L3022) for 16 h at 37°C to allow a
191 growth until the stationary phase is reached. Bacterial cells were washed once in OECD
192 medium, which is used to simulate realistic surface water conditions [32] and the cell pellet
193 collected by centrifugation was resuspended in OECD medium to obtain a realistic bacterial
194 cell concentration of 10⁸ cells/mL for wastewaters [33] according to McFarland standards
195 [34]. Before use, capillaries were heat sterilized at 160°C for 3 h. According to preliminary
196 tests, this sterilization did not affect the bactericidal properties of the capillaries (data not
197 shown).

198 **2.3.1 Agar plate test**

199 Ag_{nano} and untreated capillaries as a reference (each 25 mm length) were separately
200 incubated in 4 mL *E. coli* suspensions at RT and 200 rpm for 30 min. After incubation, the
201 capillaries were briefly washed in OECD medium to remove residual bacterial cells from the
202 inner channel of the capillary (lumen), and subsequently placed on fresh LB plates containing
203 1.5% (w/w) agar. Incubation of the plates was performed at 37°C for 24 h allowing the
204 bacteria to grow.

205 **2.3.2 Filtration test**

206 Bacterial suspensions of *E. coli* were used for filtration purposes using untreated and Ag_{nano}-
207 capillaries with accessible lengths of 100 mm, respectively. Filtration tests were performed in
208 dead-end mode. Therefore, one end of the capillary was sealed with a two-component
209 polydimethylsiloxane glue (Wirosil®, BEGO, Germany), while the other end of the capillary
210 was connected to a convenient silicon tubing. Four individual capillaries (untreated vs. Ag_{nano})
211 and independent bacterial cultures were used. For intracapillary feeding with bacterial

212 suspensions, a peristaltic pump (BVB Standard, Ismatec, Germany) was set to a constant
213 flow rate of $250 \mu\text{L min}^{-1}$. Permeates were collected and analyzed regarding the presence of
214 bacterial cells using three different microbiological methods. Adenosin triphosphate was used
215 as an indicator of bacterial metabolism and measured using a luciferase-based cell viability
216 assay as described by Lara et al. [35]. $50 \mu\text{L}$ of the permeate were mixed with $50 \mu\text{L}$ of
217 BacTiterGlo Assay (Promega No. G8231, Germany) and luminescence counts, directly
218 correlating with the amount of present ATP, were recorded using a luminescence plate
219 reader (Chameleon V, Hidex, Germany). Furthermore, the optical density of the bacterial
220 suspension at 595 nm ($\text{OD}_{595 \text{ nm}}$) was measured using a plate reader (Chameleon V, Hidex,
221 Germany). Colony forming units (CFU) were determined by plating the undiluted permeate
222 onto agar plates (Coliform Count Plate, Petrifilm, 3M, Germany) and CFUs were counted
223 after an incubation at $37 \text{ }^\circ\text{C}$ for 24 h. All experiments involving ATP assay, OD
224 measurements, and CFU tests were performed using three replicates. Obtained results
225 based on permeate samples were compared with those from the bacterial feed solution
226 which were set as 100% survival of bacteria cells.

227 Preliminary results showed that capillaries stood a bacterial load which was corresponding to
228 a membrane flux reduction of 30%, which was reached after 150 min. Consequently, filtration
229 was stopped after 150 min and back flushing was initiated to remove retained bacterial cells
230 from the inner capillary membrane surface. For this, capillaries were immersed into fresh
231 OECD medium and the peristaltic pump was operated in back flush mode with a membrane
232 flux of 1.27 mL min^{-1} for 1/10 of the filtration time, in this case i.e. 15 min. The back flushed
233 suspension was analyzed by using ATP assay, OD measurement and determination of CFU
234 as described before to determine the bacterial viability of the recovered bacterial cells. The
235 back flushed volume was determined and correlated with the filtration volume of each
236 individual capillary for further calculations.

237

238 2.3.3 Silver leaching during filtration

239 Silver leaching from Ag_{nano}-capillary membranes during filtration was analyzed by
240 determining the silver content of bacteria-free permeate samples via AAS after filtration times
241 of 30 min, 1 h and 2 h, respectively. The filtration conditions (i.e. bacterial feed concentration,
242 buffer, applied flow rate) as well as the length of Ag_{nano}-capillaries were the same compared
243 to the bacterial filtration tests described in chapter 2.3.2. For statistical significance three
244 individual capillary membranes were analyzed and permeate samples were collected on
245 three consecutive days where one filtration cycle was performed per day. After each filtration
246 cycle, back flushing was applied for membrane regeneration. For this, capillaries were
247 immersed into fresh OECD medium and the peristaltic pump was operated in back flush
248 mode with a flow rate of 1.27 mL/min for 1/10 of the filtration time (i.e. 12 min). During the
249 time between back flushing and a new filtration cycle the capillaries were held humid and
250 stored at 4 °C over night to provide stable conditions. For AAS measurements 100 µL of the
251 permeate samples were immediately acidified after filtration by adding 10 µL HNO₃ (1 %) and
252 stored at 4 °C. Afterwards, AAS measurements were performed as described in chapter 2.2
253 and untreated capillary membranes served as controls for all experiments.

254

255 3. RESULTS AND DISCUSSION

256 3.1. Surface properties of Ag_{nano}-ceramic capillary membranes

257 Zirconia capillary membranes were fabricated by extrusion as described in our previous work
258 [30] and functionalized with Ag_{nano} in a straightforward two-step procedure via direct
259 reduction of AgNO₃ on the capillary surface. As shown in Fig. 2A, the presence of Ag_{nano} on
260 the capillary changed the color of the surface from white (non-functionalized capillary made
261 of zirconia) to yellow indicating a homogeneous surface coating. SEM micrographs
262 demonstrate the presence of homogeneously distributed Ag_{nano} on the capillary outer surface

263 (Fig. 2C), whereas the microstructure of the surface of a non-functionalized capillary is
264 shown in Fig. 2B. EDX analysis confirmed that the immobilized nanoparticles on the
265 membrane surface consisted of silver (Fig. 2C, inset). In addition, SEM micrographs of the
266 inner surface of capillaries produced by using 5 mM AgNO₃ and 5 immersion cycles were
267 taken and displayed a similar Ag_{nano} loading (*Supplementary Information, Figure S1*).

268

269 **Fig. 2 Untreated and Ag_{nano}-ceramic capillary membranes**

270 Direct formation of Ag_{nano} on the surface of zirconia capillaries leads to a color change from white,
271 displaying the non-functionalized capillary, to yellow (A). Ag_{nano} were generated by 5 immersion cycles
272 using 5 mM AgNO₃ and 2 mM NaBH₄. SEM micrographs confirm the presence of homogeneously
273 distributed Ag_{nano} on the functionalized capillary (C), whereas the microstructure of a non-
274 functionalized capillary is shown in part B. EDX analysis revealed the presence of silver on the
275 functionalized membrane surface (C, inset).

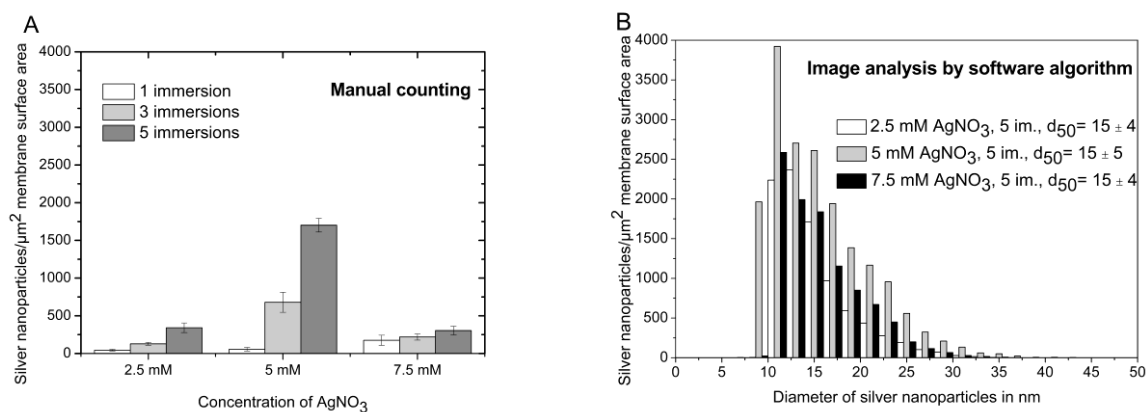

276

277 **3.2 Loading capacities of immobilized Ag_{nano} on ceramic capillary membranes**

278

279 Yielding a high Ag_{nano} loading on the membrane surface, different AgNO₃ concentrations in
280 the range between 2.5 and 10 mM and different numbers of immersion cycles (1, 3, 5 and
281 10 immersions, respectively) were applied, whereas the incubation time (5 min) and the
282 concentration of the reduction solution NaBH₄ (2 mM) were held constant. For quantification
283 of immobilized Ag_{nano} on the membrane surface, three different methods were employed:
284 manual counting of Ag_{nano} on randomly chosen sections of SEM micrographs, image analysis
285 of SEM micrographs using the software tool "Silver-Particle Analyzer" and atomic absorption
286 spectroscopy (AAS).

287 As shown in Fig. 3A, manual counting revealed that the highest loading capacity of
 288 1702 ± 91 Ag_{nano} per μm^2 capillary was achieved when using a 5 mM AgNO₃ solution in
 289 combination with five successional immersion steps, alternating membrane incubation in
 290 AgNO₃ solution and in the reduction solution NaBH₄. In general, regarding one particular
 291 AgNO₃ concentration (2.5 mM, 5 mM and 7.5 mM, respectively), increased numbers of
 292 immersion steps led to increased numbers of immobilized Ag_{nano}. Compared to an initial
 293 AgNO₃ concentration of 2.5 mM, Ag_{nano}-doped membranes fabricated by using 5 mM AgNO₃
 294 showed higher loading capacities by a factor of 1.3 (one immersion), 5.3 (three immersions)
 295 and 5.0 (five immersions), respectively. An increase of the AgNO₃ concentration to 7.5 mM
 296 did not further increase the Ag_{nano} loading on the membrane and loading capacities were in
 297 the same order of magnitude compared to 2.5 mM AgNO₃. The application of a higher
 298 concentration of 10 mM AgNO₃ and 10 immersion cycles led to the undesired formation of
 299 agglomerates of immobilized Ag_{nano}, which were inhomogeneously distributed on the capillary
 300 surface (data not shown). Providing high Ag_{nano} loadings in combination with a homogeneous
 301 membrane surface coating the application of five immersion cycles is the method of choice.

302

303 **Fig. 3 Quantification of immobilized Ag_{nano} on the capillary surface**

304 Assessment of the number of Ag_{nano} on the surface of the capillary membranes derived from manual
 305 counting of four different regions on three different SEM micrographs covering an area of $1 \mu\text{m}^2$ each
 306 (A). Ag_{nano} size distribution covering an area of $1 \mu\text{m}^2$ capillary obtained by image analysis software
 307 (B).

308

309 Additionally, an image analysis software was applied to quantify the particle size distribution
 310 of immobilized Ag_{nano} on the membrane surface (Fig. 3B). Results stood in good
 311 correspondence with the results derived from manual counting (Fig. 3A) exhibiting the
 312 highest number of Ag_{nano} on capillaries generated by using 5 immersion steps in 5 mM
 313 AgNO₃ (Fig. 3B, *Supplemental Information*, Tab. S1). Silver particle sizes were in the range
 314 of approximately 9-35 nm and the average particle diameter for the applied production
 315 conditions was calculated to be $d_{50} = 15$ nm (Fig. 3B) indicating that different AgNO₃
 316 concentrations from 2.5 to 7.5 mM lead to similar silver particle sizes and morphologies.

317 Referring to a geometric surface area of 1 mm² on Ag_{nano}-capillaries, the active silver surface
 318 on the outer and inner surface of the capillary was calculated to allow an assessment of the
 319 total silver surface that can interact with the filtrated bacterial cells. For the calculation based
 320 on the particle area that was recognized by the analysis software, it was assumed that all
 321 Ag_{nano} were spherical and the contact area between the nanoparticles and the capillary
 322 surface was negligible. Again, the highest accessible silver surface area of 0.594 mm² was
 323 present on capillaries treated with 5 mM AgNO₃, whereas capillaries treated with 2.5 mM and
 324 7.5 mM exhibited a total silver surface of 0.269 and 0.314 mm², respectively. Implicating the
 325 density of silver (10.49 g/cm³), total amounts of silver were calculated and capillaries treated
 326 with 5 mM AgNO₃ and 5 immersion steps yielded the highest silver loadings of 20 ng per
 327 1 mm² geometric surface area (Tab. 1).

328

329 **Tab. 1: Accessible silver surface area and total amount of immobilized silver on 1 mm²**
 330 **geometric surface area of Ag_{nano}-capillaries**

Conditions for the immobilization of silver nanoparticles	Accessible silver surface area in mm ^{2*}	Total amount of silver in ng**
2.5 mM AgNO ₃ , 5 immersions	0.269 ± 0.076	8.23 ± 2.51

5 mM AgNO₃, 5 immersions	0.594 ± 0.129	20.00 ± 5.08
7.5 mM AgNO₃, 5 immersions	0.314 ± 0.101	9.95 ± 3.90

331

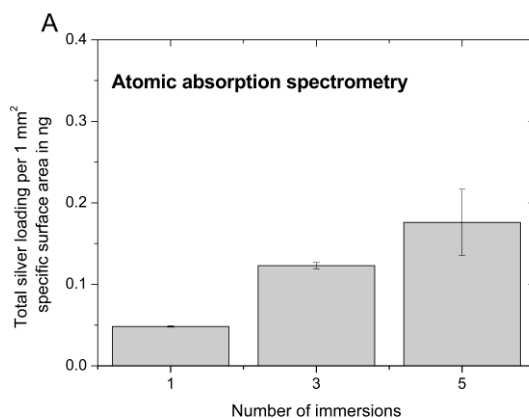

332 ***The accessible silver surface area was calculated based on software-calculated pixel areas and on the**
333 **assumption that all Ag_{nano} were spherical.**

334 **** The total amount of immobilized Ag_{nano} was calculated considering the density of silver (10.49 g/cm³).**

335

336 The two methods, manual counting and software generated particle counts, only consider the
337 Ag_{nano} distribution on the geometric outer and inner surface of the ceramic capillary based on
338 SEM micrographs. The possible penetration of Ag_{nano} into the pores of the membrane
339 material was therefore not considered. With regard to this, we additionally determined the
340 total silver loadings of capillaries treated with 5 mM AgNO₃ by AAS. Using this method, an
341 acidic digestion ensured the total release of silver from the capillaries. With regard to the
342 surface of the pores, the measured amounts of total silver loadings were correlated to the
343 specific surface area of Ag_{nano}-capillaries of 7.05 m²/g (*Supplemental Information, Table S2*).
344 The obtained AAS results were comparable to the results derived from counting: total Ag_{nano}
345 loadings increased with the number of immersions featuring 0.048 ± 0.001 ng silver/mm²
346 specific surface area for 1 immersion, 0.123 ± 0.004 ng silver/mm² of capillary specific
347 surface area for 3 immersions and 0.176 ± 0.040 ng silver/mm² of capillary specific surface
348 area for 5 immersions (Fig. 4 A). It is noticeable that the calculated amount of bioactive silver
349 based on pixel-generated data of 20 ng per 1 mm² geometric surface area was significantly
350 higher than the total amount of silver of 0.18 ng per 1 mm² specific surface area that was
351 measured via AAS. The discrepancy of the results can be explained by the different
352 reference membrane areas that were applied. Results from the counting method must be
353 referred to the geometric surface area, since only Ag_{nano} on the outer membrane of the
354 capillaries were considered for the counting. Fig. 4B and Fig. C clearly display that Ag_{nano}
355 penetrated to a large extent into the pores of the capillary membrane. For that reason, for the

356 determination of total silver loadings via AAS, the specific surface area determined via
357 nitrogen-adsorption was considered as a reference leading to significantly lower values.
358 Simultaneously, the deep penetration of Ag_{nano} into the pores displays an advantage by
359 enhancing the accessible interaction surface of bactericidal Ag_{nano} and filtrated bacteria.

360

361

362 **Fig. 4: Total amount of immobilized Ag_{nano} per 1 mm² specific surface area measured via AAS**
363 **and penetration of immobilized Ag_{nano} into the membrane material (5 mM AgNO_3 , 5 immersions)**

364 AAS revealed total silver loadings of capillary membranes that were produced using 5 mM AgNO_3 and
365 varying numbers of applied immersions (A). Cross section of a Ag_{nano} -doped capillary membrane
366 where the intensity of the yellow coloration is correlated with the content of immobilized silver
367 nanoparticles (B, C).

368

369 Membrane pore size distributions as well as pore volumes and mechanical properties of
370 untreated and Ag_{nano} -capillaries (5 mM AgNO_3 , 5 immersion steps) were determined by
371 nitrogen adsorption isotherms (BET-BJH evaluation) and bending strength tests (3-point

372 bending test). Results showed that the additional Ag_{nano}-functionalization did not significantly
373 alter both, the membrane pore sizes and the mechanical properties of the zirconia capillaries
374 [30] providing an efficient filtration performance and good mechanical properties for handling
375 purposes (*Supplemental Information*, Table S2, Figure S2).

376

377 **3.3 Bactericidal properties of Ag_{nano}-capillaries under batch and filtration conditions**

378 Bactericidal properties of Ag_{nano}-capillaries were analyzed by incubating untreated and
379 Ag_{nano}-capillaries in bacterial suspensions of *E. coli* for 30 min at room temperature. As
380 expected, bacterial growth was only visible close to the untreated capillaries, whereas Ag_{nano}-
381 capillaries prevented the growth of *E. coli* cells displaying significant bactericidal properties
382 (Fig. 5).

383

384 **Fig. 5 Bactericidal properties of Ag_{nano}-capillary membranes**

385 An agar plate test displays the bactericidal properties of the Ag_{nano}-capillaries (5 mM AgNO₃,
386 5 immersion cycles) against Gram-negative *E. coli*. While considerable bacterial growth was observed
387 close to the untreated capillaries, the Ag_{nano}-capillaries exhibited no bacterial growth.

388

389 For realistic fresh water filtration conditions the standardized OECD medium was chosen for
390 the preparation of the bacterial feed, since it is used for experiments with the freshwater
391 algae *Pseudokirchneriella subcapitata* [36]. Filtration of an *E. coli* suspension was performed
392 in dead-end mode by intracapillary feeding at an initial flow rate of 250 µL/min for 2.5 h using

393 100 mm capillaries (exhibiting a geometric surface area of 750 mm²) and the resulting
394 permeates of untreated and Ag_{nano}-capillaries were analyzed every 30 min regarding
395 bacterial viability by measuring ATP levels, CFU and OD_{595nm}. Results showed highly efficient
396 filtration efficiencies for untreated and Ag_{nano}-capillaries achieving a bacterial retention of
397 nearly 100 % which corresponds to a log₁₀ reduction value (LRV) of 8 (Fig. 6 A, B). No CFUs
398 were detected after plating the permeate samples onto agar plates and ATP and OD_{595nm}
399 levels of the permeate samples were comparable to the buffer controls indicating a clear and
400 bacteria-free solution (data not shown). Achieving log₁₀ reduction levels of >6, the here
401 presented capillaries accomplish the bacteria filter criterion for safe and clean drinking water
402 according to the U.S. Environmental Protection Agency [37].

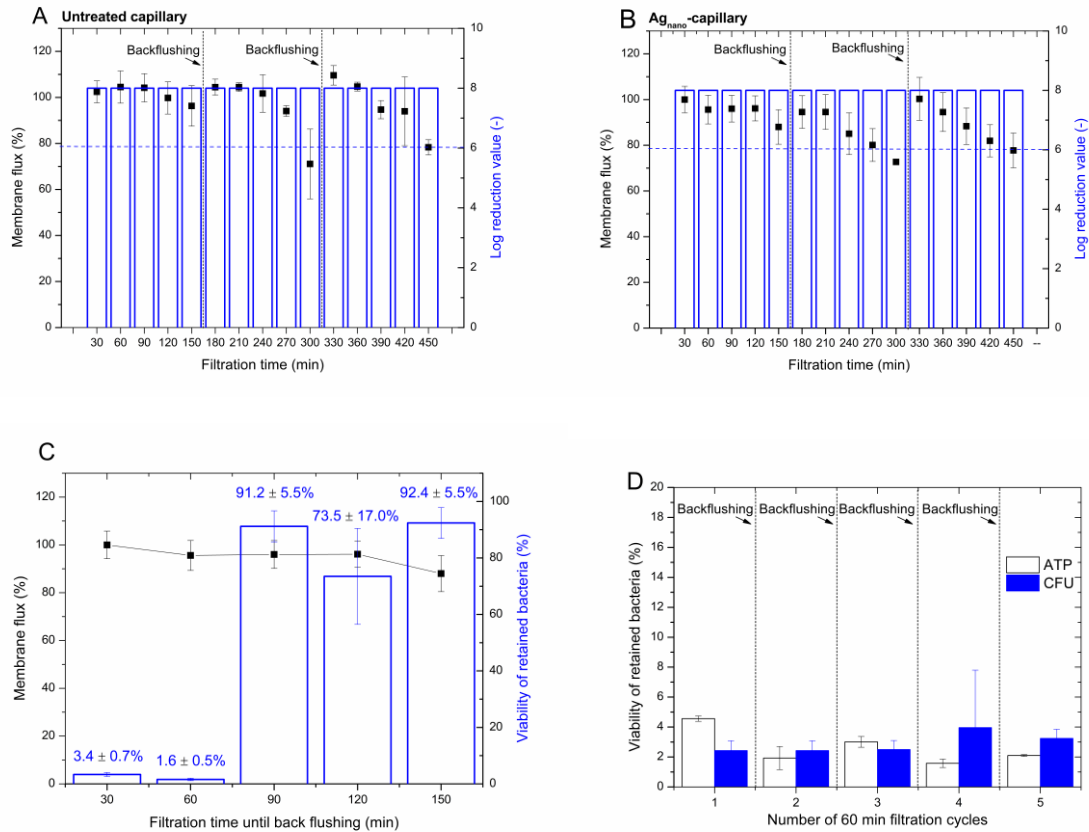

403 Since the membrane flux decreased during filtration, back flushing was induced for
404 membrane regeneration after the filtration of approximately 3x10⁹ bacterial cells per capillary
405 (750 mm² geometric surface area), which corresponds to a filtration time of 2.5 h. Back
406 flushing was applied for 1/10 of the filtration time and filtration efficiencies were recovered by
407 reaching 95-100% of the initial membrane flux (Fig. 6 A, B).

408 Since both, untreated and Ag_{nano}-capillaries, featured similar filtration properties, the
409 assumed benefit of the Ag_{nano}-immobilization is the inhibition of the initial attachment of living
410 bacteria [38, 39] to the capillary surface and the inhibition of initial biofilm formation. In
411 general, after initial attachment, bacteria start to secrete extracellular polymeric substances
412 providing a matrix for other bacteria to embed and build a biofilm [40]. This biofilm leads to
413 pore blocking which is followed by an increase of the transmembrane pressure and operating
414 time leading to lower filtration efficiencies. Creating a strong bactericidal surface by using an
415 Ag_{nano} coating, bacteria are assumed to die when coming into contact with the capillary
416 membrane before the expression of biofilm components will be initiated and dead bacteria
417 will be removed by operating the pump in back flush mode [41].

418 To analyze the viability of the retained bacteria, the recovered bacteria from back flushing
419 were analyzed regarding ATP levels and CFU. Unfortunately, bacteria that were recovered
420 from Ag_{nano}-capillaries during back flushing after 150 min filtration were found to be viable as
421 measured by ATP levels and CFU. The amount of filtrated bacteria was probably too high so
422 that the contact of bacterial cells with the bactericidal Ag_{nano} surface could not be assured
423 (data not shown).

424 Therefore, individual Ag_{nano}-capillaries were tested for filtration times of 30, 60, 90, 120 and
425 150 min to identify the maximum filtration time that ensured the death of retained bacteria.
426 Back flushing after 30 min and 60 min filtration time showed that recovered *E. coli* cells from
427 Ag_{nano}-capillaries were dead displaying marginal bacterial ATP levels of 3.4 and 1.6 % in
428 comparison to reference bacteria that were recovered from untreated capillaries (Fig. 6C).
429 Capillaries that were used for longer filtration times of >60 min were not capable in killing
430 bacterial cells at the inner membrane surface of the capillaries as shown by determined ATP
431 levels (Fig. 6C). Back flushing of Ag_{nano}-capillaries should therefore be initiated after a
432 maximum filtration time of 60 min, corresponding to a bacterial load of 6x10⁸ bacterial
433 cells/750 mm² geometric capillary surface area.

434 Understanding the stability of each individual bactericidal Ag_{nano} membrane coating, Ag_{nano}-
435 capillary membranes were tested for five consecutive filtration cycles of 60 min each, while
436 back flushing was initiated after each cycle. Microbiological results showed that bacterial
437 viability was decreased to 2-5 % in relation to the reference bacteria that were recovered
438 from untreated capillary membranes as analyzed by ATP levels and CFU indicating a stable
439 bactericidal membrane surface at suitable filtration times of 60 min (Fig. 6D).

440

441

442 **Fig. 6 Filtration efficiencies of untreated and Ag_{nano}- capillaries**

443 Filtration in dead-end mode by intracapillary bacterial feeding was performed using untreated (A) and
 444 Ag_{nano}-capillary membranes (B) resulting in bacterial retention values of log₁₀ 8. The blue, dashed line
 445 indicates the requirements on safe and clean drinking water of log reduction values of 6 according to
 446 the U.S. Environmental Protection Agency. Back flushing was applied after a filtration time of 2.5 h,
 447 corresponding to approximately 3x10⁹ cells, resulting in regained membrane fluxes of 95-100%. No
 448 significant differences in bacterial retention rates ensuring log reduction values of 8 were obtained for
 449 untreated versus Ag_{nano}-capillary membranes (A, B).

450 Individual Ag_{nano}-capillaries were used for different filtration times to identify the maximum filtration
 451 time that still guaranteed the killing of retained bacteria: filtration times of ≤60 min allowed the killing of
 452 filtrated bacteria (C). Regarding the stability of the bactericidal membrane coating, Ag_{nano}-capillaries
 453 were efficient in killing retained bacteria after five consecutive filtration cycles of 60 minutes each,
 454 where back flushing was applied for membrane regeneration (D).

455

456 Similar results were obtained by Liu et al. [20] showing that a silver-nanoparticle-decorated
 457 polysulfone membranes exhibited anti-adhesiv properties in comparison to unfunctionalized
 458 polysulfone membranes. Although the authors reported similar retention rates for
 459 unfunctionalized and silver-functionalized polysulfone membranes, significantly more
 460 bacteria were detached during rinsing experiments from the silver-decorated membranes
 461 than from untreated membranes. However, our back flushing results (Fig. 6C) also showed

462 that longer filtration times >60 min were not recommendable, since bacterial killing was not
463 ensured anymore. The bacterial filter cake was probably too thick to allow a contact-induced
464 killing of bacteria by Ag_{nano}.

465 Silver contamination of water is an environmental predicament. Since silver is proved to be
466 toxic against several freshwater organisms such as *Daphnia magna* [42] and may lead to
467 safety concerns [43], its release into the environment needs to be accurately monitored.

468 Thus, the release of silver from the Ag_{nano}-capillaries during filtration and silver maximum
469 contaminant levels were determined. Therefore, samples from the filtrated permeates of
470 three individual capillaries were removed after 30 min, 60 min and 120 min of filtration on
471 three consecutive days and analyzed by AAS. AAS measurements revealed that the silver
472 release was highest at the beginning of the filtration on each individual day. After the first
473 burst release after 30 min of filtration on the first day where $400 \pm 3 \mu\text{g/L}$ of silver were
474 released, silver leaching progressively decreased reaching values of $34 \pm 0 \mu\text{g/L}$ already
475 after 60 min of filtration and only $21 \pm 17 \mu\text{g/L}$ at the last measurement after 120 min of
476 filtration (Fig. 7). Among the filtration cycles, capillaries were stored under humid conditions
477 at 4°C overnight until filtration was started again. The storage induced a continuous release
478 of silver from the capillary, which was then released at the following filtration cycles, which
479 explains the recurring increases of silver release in the beginning of each filtration cycle.
480 High standard deviations result from the phenomenon that small pieces of the capillaries got
481 lost and were measured in the permeate samples. The maximum contaminant level for silver
482 in drinking water is 50 $\mu\text{g/L}$ as set by the World Health Organization (WHO), whereas “under
483 special situations where silver salts are used to maintain the bacteriological quality of
484 drinking-water higher levels of up to 100 $\mu\text{g/L}$ can be tolerated without risk to health” [44].
485 Although silver was continuously released during filtration, WHO requirements were fulfilled
486 already after 1 h of filtration when silver contaminant levels of $34 \pm 0 \mu\text{g/L}$ were reached.

487 In addition to the eco-toxicological aspect, the loss of the bactericidal coating displays a
488 drawback, because it reduces the operating time and requires a frequent replacement of the
489 coating or the complete membrane. Total silver loading capacities of Ag_{nano}-capillaries of
490 411.64 ± 94.88 µg silver/100 mm capillary were determined by AAS. The filtration experiment
491 showed that 0.23 ± 0.05 % of the initial silver loading were released after the first 30 minutes
492 of filtration and amounts of 0.01 ± 0.05 % were released after 420 minutes of filtration on the
493 third day. The total silver release during the three-day experiment was determined to be
494 0.81 ± 0.43 % of the initial silver content that was immobilized on each capillary displaying a
495 very good stability of the bactericidal Ag_{nano} coating.

496

497 **Fig. 7 Silver release during filtration**

498 Silver contents in the permeate samples of three individual capillaries of 100 mm lengths were
499 analyzed using AAS to determine the silver release from the Ag_{nano}-capillaries. For this, permeate
500 samples were removed after 30 min, 60 min and 120 min of filtration on three consecutive days. Silver
501 leaching was highest at the beginning of the three filtration cycles and decreased progressively during
502 each filtration cycle.

503

504 Leaching of immobilized silver has also been demonstrated by Chou et al. [45] who analyzed
505 the stability of an Ag_{nano} coating on cellulose acetate hollow fiber membranes. A 180 days
506 static immersion in water decreased the silver content on the membrane surface by 90%, but
507 still an antibacterial effect against *E. coli* and *S. aureus* was evident. In contrast, after

508 permeating with water for 5 days, a significant higher and faster loss of silver was determined
509 and no antibacterial effect was measurable anymore. Others studies also reported rapid
510 depletions of silver from membrane surfaces after relatively short filtration periods (0.4 L/cm²)
511 and the soon loss of antibacterial and antiviral activities [6]. The here presented capillaries
512 were capable of killing bacteria during filtration for at least five consecutive filtration cycles of
513 60 min and the silver release from the membrane after the first 30 min of filtration fulfilled the
514 requirements on eco-toxicological demands.

515

516 **5. CONCLUSIONS**

517 Porous ceramic capillaries made of zirconia were functionalized with broadband bactericidal
518 Ag_{nano} for utilization as small-sized water purification modules exhibiting durable antibacterial
519 properties. The immobilization of Ag_{nano} was performed via direct reduction of silver nitrate to
520 metallic Ag_{nano} on the surface of the capillaries. This straightforward procedure led to high
521 silver loadings of up to 1700 Ag_{nano} per μm² capillary surface when using 5 mM AgNO₃ and
522 5 immersion cycles and could also be transferred to other oxide and non-oxide ceramics,
523 such as aluminum oxide or silicon carbide. Total silver loadings as determined by AAS were
524 found to be 0.18 ng silver per 1 mm² specific surface area and 20 ng silver per 1 mm²
525 geometric surface area as calculated based on nanoparticle-covered membrane surface
526 areas.

527 Zirconia capillaries exhibited excellent filtration performances obtaining bacterial retention
528 rates of log₁₀ reduction values of 8. Back flushing cycles of 1/10 of the filtration time were
529 suggested for membrane regeneration leading to regained filtration efficiencies of 95-100 %.

530 Creating a strong bactericidal surface, immobilized Ag_{nano} on the zirconia surface efficiently
531 killed bacteria during filtration for filtration times of up to 60 min corresponding to 6x10⁸
532 filtrated bacterial cells/750 mm² capillary surface. A subsequent back flushing cycle ensured

533 the removal of dead cells from the membrane surface leading to the regeneration of filtration
534 efficiencies and allowed the application for consecutive filtration cycles. Release of silver
535 during filtration was analyzed and was moderate leading to silver contaminant levels of
536 34 µg/L after one hour of filtration (250 µL/min).

537 Displaying strong bactericidal properties, the described ceramic-silver composite might be
538 beneficial for several disinfection strategies, for example when applied for the coating of
539 medical devices or for areas in which germ-free surfaces are necessary.

546 **SUPPLEMENTAL INFORMATION**

547 **1) Silver nanoparticle loading capacities on capillary membranes**

548

549 **Fig. S1: SEM micrograph of the inner surface of a capillary produced by using 5 mM AgNO₃**
550 **and 5 immersion steps.**

551

552 **Tab. S1: Ag_{nano} loadings obtained by image analysis software for capillaries produced using**
 553 **2.5 mM, 5.0 mM and 7.5 mM AgNO₃ and 1, 3 and 5 immersion steps**

Silver nanoparticles/ μm^2 membrane surface area	2.5 mM AgNO ₃	5 mM AgNO ₃	7.5 mM AgNO ₃
1 immersion	147 ± 82	93 ± 83	276 ± 78
3 immersions	371 ± 148	1069 ± 42	1110 ± 417
5 immersions	466 ± 807	2652 ± 741	759 ± 394

554

555 **2) Porosity and mechanical properties of Ag_{nano}- and untreated capillaries**

556 *Materials and Methods: Pore size distribution, pore volume and specific surface area*

557 The pore size distribution, pore volume and specific surface area of the untreated and Ag_{nano}-
 558 doped capillaries were calculated from nitrogen adsorption isotherms according to the
 559 method of Brunauer et al. (BET) [46]. Adsorption isotherms have been recorded at -196°C
 560 and the calculation of the specific surface areas was performed using a BELSORP-mini (BEL
 561 Japan Inc., Japan) and the provided software (BELMaster). All samples were vacuum dried
 562 at <0.5 mbar and 120°C for 2 h prior to BET analysis.

563 *Material and Methods: Mechanical strength*

564 According to DIN EN 843-1 the mechanical strength of Ag_{nano}-doped capillaries compared to
 565 non-functionalized capillaries (reference) was obtained by three-point bending tests (Roell
 566 Z005, Zwick). These measurements were performed using a Zwick Z005 testing machine
 567 provided with a load cell for 5 kN (piezoelectric force sensor). The capillary sample (25 mm
 568 length) was placed into the centre of a sample holder featuring an 8 mm distance between
 569 the support rollers. The bending strength σ_F was calculated as described in our previous

570 study [30]. 30 samples for each series were tested to achieve a significant average bending
571 strength.

572

573 *Results: Porosity and mechanical properties of Ag_{nano}- and untreated capillaries*

574 The total pore volume of untreated capillaries of $0.07 \pm 0.01 \text{ cm}^3 \text{ g}^{-1}$ differed markedly from
575 Ag_{nano}-capillaries showing a significant higher total pore volume of $0.12 \pm 0.01 \text{ cm}^3 \text{ g}^{-1}$, while
576 the specific surface area was similar for both samples ($7.05 \text{ m}^2 \text{ g}^{-1}$ versus $8.08 \text{ m}^2 \text{ g}^{-1}$). The
577 mechanical properties were expected not to be altered after immobilization with Ag_{nano} and
578 three-point bending tests revealed similar bending strengths of 48.1 MPa for untreated and
579 53.5 MPa for Ag_{nano}-capillaries with relatively high Weibull modules of 14.2 and 8.0,
580 respectively (Tab. S2). Therefore, silver-doping did not alter the membrane properties
581 leading to promising candidates for sustainable bacterial filtration if a sufficient antibacterial
582 activity is achieved.

583 Figure S2 presents the pore size distributions of untreated (A) and Ag_{nano} (B) capillary
584 membranes determined by BET-BJH. Untreated and Ag_{nano}-capillaries exhibited the same
585 pore size range of 24-196 nm, whereas the median pore size was 80 nm for untreated and
586 100 nm for Ag_{nano}-capillaries.

587 **Tab. S2: Membrane properties of untreated and Ag_{nano}-capillaries**

588 BET analysis and three-point bending tests revealed similar membrane properties of untreated and
589 Ag_{nano}-capillaries displaying optimal properties for aspired bacterial filtration with median pore sizes of
590 80 and 100 nm and a sufficient mechanical stability showing bending strength values of ~50 MPa.
591

592

	Untreated capillary	Ag_{nano}-capillary 5 mM AgNO₃ 5 immersions
Pore diameter in nm	24-196*	24-196*
Median pore diameter (d₅₀) in nm	80	100
Total pore volume in cm³g⁻¹	0.07 ± 0.01	0.12 ± 0.01

Specific surface area in m^2g^{-1}	7.05 ± 0.20	8.08 ± 1.04
Bending strength σ_0 in MPa	48.1	53.5

Tab. 1: Accessible silver surface area and total amount of immobilized silver on 1 mm² geometric surface area of Ag_{nano}-capillaries

Conditions for the immobilization of silver nanoparticles	Accessible silver surface area in mm^{2*}	Total amount of silver in ng**
2.5 mM AgNO₃, 5 immersions	0.269 ± 0.076	8.23 ± 2.51
5 mM AgNO₃, 5 immersions	0.594 ± 0.129	20.00 ± 5.08
7.5 mM AgNO₃, 5 immersions	0.314 ± 0.101	9.95 ± 3.90

*The accessible silver surface area was calculated based on software-calculated pixel areas and on the assumption that all Ag_{nano} were spherical.

** The total amount of immobilized Ag_{nano} was calculated considering the density of silver (10.49 g/cm³).
