## ABSTRACT

The permeability barrier of the outer membrane in Gram-negative bacteria possess an inherent defense towards antibiotics and is subject of study using multidisciplinary approaches and cutting-edge techniques. In this study, a medium-high throughput assay based on liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) was optimized and applied for comparing the degree of uptake of antibiotics with different modes of action into *E. coli* and *P. aeruginosa*. This method allowed the elucidation of time-course profiles of rapidly accumulated compounds and helped to differentiate accumulation profiles of nine antibiotics between the two Gram-negative species. The strain transferability of this assay allows the systematic assessment of the uptake of a broad range of compounds in different microorganisms.

Apart from an increased impermeability, pathogenic bacteria quickly adapt metabolically to cope with a wide variety of environmental stresses, including antibiotic stress. Exposure to sub-lethal but constant concentrations of antibiotics in the environment plays an important role in enabling bacteria to make use of tolerance and resistance traits. In this study, the metabolic profile of wild type *P. aeruginosa* treated with different classes of antibiotics at sub-lethal concentrations showed important differences under a short exposure of two hours, and a long exposure of more than seven hours. *P. aeruginosa* maintained high levels of virulence-related metabolites, such as rhamnolipids, as a quick response to sudden antibiotic stress, indicating the readiness of bacteria to adapt quickly to environmental challenges.

Fluoroquinolones, among the most potent antibiotics to date, are known to propitiate diverse bacterial responses, such as growth inhibition, biofilm production, and increased oxidative-stress response. However, these effects are associated to their potent activity and thought to be due to target interactions. In this study, two *P. aeruginosa* strains, one fluoroquinolone-susceptible with MIC of 0.15 µg/mL and one fluoroquinolone-resistant with MIC of 29.83 µg/mL, were subjected to an LC-MS/MS-based untargeted metabolomics analysis and provided with evidence of indirect responses to increasing concentrations of ciprofloxacin. In spite of the lack of an active target, the resistant mutant showed important off-target effects in response to ciprofloxacin accumulation. Those secondary-target effects were related to the virulence regulation of *P. aeruginosa*, such as the quorum sensing response, and to alterations in lipid metabolism and peptidoglycan assembly, and were correlated with ciprofloxacin accumulation.

**Key words:** metabolomics, antibiotic uptake, sub-inhibitory concentrations, off-target effects, secondary-target effects, quorum sensing

## ZUSAMMENFASSUNG

Die äußeren Membran von Gram-negativen Bakterien stellt eine inhärente Permeabilitätsbarriere gegen Antibiotika dar und ist daher Gegenstand von Untersuchungen mit multidisziplinären Ansätzen und modernsten Techniken. In dieser Studie wurde ein auf Flüssigkeitschromatographie-gekoppelter Tandem-Massenspektrometrie (LC-MS/MS) basierender Assay mit mittlerem Durchsatz optimiert und eingesetzt, um die Aufnahme von Antibiotika mit unterschiedlichen Wirkmechanismen in *E. coli* und *P. aeruginosa* zu untersuchen. Die Methode ermöglichte, den Zeitverlauf der Aufnahme zu verfolgen und die Akkumulationsprofile von neun Antibiotika zwischen beiden Gram-negativen Spezies zu vergleichen. Der Assay erlaubt damit die systematische Bewertung der Aufnahme eines breiten Spektrums von Verbindungen in verschiedenen Mikroorganismen.

Pathogene Bakterien passen ihren Metabolismus schnell an, um auf eine Vielzahl von Umweltbedingungen wie Antibiotikastress zu reagieren. Die Exposition von Bakterien mit subletalen, konstanten Konzentrationen von Antibiotika spielt eine wichtige Rolle bei der Ausbildung von Toleranz- und Resistenzeigenschaften. In dieser Studie zeigte das metabolische Profil eines Wildtypstamms von *P. aeruginosa*, der mit verschiedenen Klassen von Antibiotika in subletalen Konzentrationen behandelt wurde, wichtige Unterschiede zwischen einer kurzen Exposition von zwei Stunden und einer langen Exposition von mehr als sieben Stunden. Als schnelle Reaktion auf plötzlichen Antibiotika-Stress wurden hohe Konzentrationen virulenzbezogener Metabolite, wie z. B. Rhamnolipide, detektiert. Dies belegt die Fähigkeit der Bakterien, schnell auf sich verändernde äußere Umgebungen zu reagieren.

Fluorchinolone, die eine hochwirksame Antibiotikaklasse darstellen, sind dafür bekannt, daß sie verschiedene bakterielle Reaktionen induzieren, wie z.B. verringertes Wachstum, Biofilmproduktion und eine erhöhte oxidative Stressreaktion. Es wird angenommen, dass diese Effekte eine Folge spezifischer Target-Interaktionen sind. In dieser Studie wurden zwei *P. aeruginosa*-Stämme, ein Fluorchinolon-sensitiver mit einer minimalen Hemmkonzentration (MHK) von 0,15 µg/mL und eine Fluorchinolon-resistente Mutante mit einer MHK von 29,83 µg/mL, einer LC-MS/MS-basierten, ungerichteten Metabolomics-Analyse unterzogen. Trotz der fehlenden Target-Interaktion zeigte die resistente Mutante wichtige Off-Target-Effekte als Reaktion auf die Ciprofloxacin-Akkumulation. Diese Sekundär-Effekte standen im Zusammenhang mit der Virulenzregulation von *P. aeruginosa*, wie z. B. der Quorum-Sensing-Antwort. Weiterhin waren Veränderungen im Lipidstoffwechsel und der Peptidoglykan-Assemblierung mit der Ciprofloxacin-Akkumulation korreliert.

**Schlagworte:** Metabolomik, Antibiotika-Aufnahme, sub-inhibitorische Konzentrationen, Off-Target-Effekte, Sekundär-Target-Effekte, Quorum Sensing

log2-FC	Fold change of log2-transformed data
logn	Logarithm base n
LOME	Lomefloxacin
LPE	Lyso-phosphatidylethanolamine
LPG	Lyso-phosphatidylglycol
LPS	Lipopolisaccharide
LSU	Large subunit
MA	Macrolide
MDR	Multi-drug resistant
MERO	Meropenem
MIC	Minimum inhibitory concentration
MOA	Mode of action

MRM	Multiple-reaction monitoring
m-RNA	Messenger ribonucleic acid
MS	Mass spectrometry
MTA	Methylthio adenosine
MurNac	N-acetylmuramic acid
m/z	Mass-to-charge ratio of the molecular ion
NAD	Nicotinamide adenine nucleotide
NADP+	Adenine dinucleotide phosphate
NIC	Non-inhibitory concentration
NMR	Nuclear magnetic resonance spectrometry
Nuc	Nucleotide
OD <sub>600</sub>	Optical density at $\lambda = 600$ nm
OM	Outer membrane
PBP	Penicillin binding proteins
PC	Principal component
PCA	Principal component Analysis
PE	Phosphatidylethanolamine
PEG	Polyethylene glycol
PG	Phosphatidylglycol
Phen	Phenazine
Phenyl	Phenylalanine
PhosLip	Phospholipid
PLS	Partial-least squares
PQS	Pseudomonas quorum sensing
-PQS	Congener of 2-alkyl-3-hydroxy-4-quinolones
PTC	Peptidyl transferase center
Q	Single quadrupole
Q1, Q2, Q3	First, second and third quadrupole, respectively
-QNO	Congener of 2-alkyl-hydroxyquinoline-N-oxides
QQQ	Triple quadrupole
Rha	Rhamnolipid
RNA	Ribonucleic acid
ROS	Reactive oxygen species
r-RNA	Ribosomal ribonucleic acid
RT	Retention time
SE	Short exposure
SNP	Single nucleotide polymorphism
SRM	Selected-reaction monitoring
SSU	Short subunit
sub-MIC	Concentrations under the minimum inhibitory concentration
TCA	Tricarboxylic acid
TIC	Total ion chromatogram
TOBRA	Tobramycin
ToF	Time of flight
tRNA	Transfer ribonucleic acid
UDP	Uridine diphosphate
UPLC	Ultra-Performance Liquid Chromatography
WT	Wild type

# 1. INTRODUCTION

## 1.1 Emerging infectious diseases

Infectious diseases are a major cause of death globally, and a leading cause of death in low-income countries (Tacconelli et al. 2018; World Health Organization 2001). Among the most deadly infectious diseases worldwide are lower respiratory infections, diarrheal diseases, tuberculosis and AIDS. Additionally, emerging infectious diseases (EID) have been increasing with alarming speed, and our ability to find effective therapeutics has been surpassed (Ogden, AbdelMalik, and Pulliam 2017). The difficulty of combating infections lies mostly in the emergence of new infectious agents, the re-emergence of known infectious agents previously under control, the gain in the geographical distribution of known infectious diseases, and the increasing resistance of pathogens to the available antimicrobial drugs (World Health Organization 2001).

Antimicrobial resistance has been unprecedentedly addressed worldwide by national governments and international organizations. In order to support the implementation of the Global Action Plan on Antimicrobial Resistance, in 2016, the World Health Organization (WHO) declared a priority pathogens list of antibiotic-resistant bacteria (see Table 1.1). The WHO prioritization list suggests that drug research and development should focus on new antibiotics specifically active against tuberculosis and multi-drug resistant (MDR) Gram-negative bacteria responsible with high morbidity in both high-income and low- and middle-income countries (Tacconelli et al. 2018).

Table 1.1 World Health Organization Priority Pathogens List

Level	Pathogens
Priority 1: Critical	<i>Acinetobacter baumannii</i> , carbapenem-resistant <i>Pseudomonas aeruginosa</i> , carbapenem-resistant <i>Enterobacteriaceae</i> , carbapenem-resistant, 3G-cephalosporin resistant
Priority 2: High	<i>Enterococcus faecium</i> , vancomycin-resistant <i>Helicobacter pylori</i> , clarithromycin-resistant <i>Salmonella spp.</i> , fluoroquinolone-resistant <i>Staphylococcus aureus</i> , vancomycin-resistant, methicillin-resistant <i>Campylobacter spp.</i> , fluoroquinolone-resistant <i>Neisseria gonorrhoeae</i> , 3G-cephalosporin resistant, fluoroquinolone-resistant
Priority 3: Medium	<i>Streptococcus pneumoniae</i> , penicillin-non-susceptible <i>Haemophilus influenzae</i> , ampicillin-resistant <i>Shigella spp.</i> , fluoroquinolone-resistant

3G: 3rd generation

## 1.2 Antibiotics: mode of action and resistance mechanisms

Among antimicrobial drugs, some compounds target bacteria, viruses, fungi or parasites, and they are designated as antibiotics, antivirals, antifungals and antiparasitic drugs, respectively. Most of antibiotics are low-molecular-weight compounds (<1000 Da) with selective activity against bacteria. Antibiotics are classified into two big groups according to their lethality: they are called bacteriostatic when the growth and proliferation of bacteria are inhibited without killing, and they are called bactericidal when the compound leads to a killing effect. The way that antibiotics act against bacteria lies in their mechanism of action, also known as their mode of action (MOA).

### 1.2.1 Mode of action of major classes of antibiotics

#### 1.2.1.1 Disruption of membrane integrity

The construction of the cell envelopes of Gram-positive and Gram-negative bacteria are very distinctive. While Gram-positive bacteria possess a bacterial membrane and a complex peptidoglycan layer, Gram-negative bacteria possess an inner membrane (IM), a peptidoglycan layer, and an outer membrane (OM) (see Figure 1.1). Agents that can disrupt the integrity of bacterial membranes are considered bactericidal, and there is a subgroup of molecules with sufficient selectivity to bacterial membranes over eukaryotic, human cell membranes to be considered for therapeutic use.

Figure 1.1 Cell envelopes of Gram-negative and Gram-positive bacteria. BL: Braun's lipoprotein, LTA: lipoteichoic acid, LPS: lipopolysaccharide, WTA: wall teichoic acid. From (Walsh and Wenciewicz 2016)

Polymyxins, such as colistin and polymyxin B, are last resort antibiotics against Gram-negative bacteria (Kaye et al. 2016). They present electrostatic interaction with lipopolysaccharides (LPS) to disrupt the OM integrity, then passing through the IM to disrupt it as well (Poirel, Jayol, and Nordmann 2017).

For instance, human defensins, produced in different tissues such as skin, small intestine, reproductive tract, kidney, among others, are disulfide-rich small proteins that kill bacteria by their insertion and accumulation in bacterial membranes. Daptomycin is believed to form micelles and insert into bacterial membrane, leading to the formation of pores and depolarization of the membrane (Hojati et al. 2002). Similarly, surfactin can form aggregates in bacterial membranes to make pores that induce potassium ion (K<sup>+</sup>) efflux (Carrillo et al. 2003). Recently, it was found that daptomycin binds to bactoprenyl-bound precursors in the presence of phosphatidylglycerol (PG) to form a tri-partite complex, interfering with lipid II biosynthesis (Grein et al. 2020).

Other antibiotics are known to have dual mechanisms. For instance, some lantibiotic peptides, such as Nisin, have a high affinity to lipid II (see 1.2.1.2 Blockade of peptidoglycan assemble) and aggregate in the IM in pore-like structures causing membrane perturbation. Similarly, some lipoglycopeptide antibiotics, such as teicoplanin, inhibit the synthesis of cell wall peptidoglycan by interacting with the D-ala-D-ala terminal of the UDP-MurNac-pentapeptide, as their major MoA (Parenti 1986), and also aggregate to disrupt the IM integrity (Kang and Park 2015).

#### *1.2.1.2 Blockade of peptidoglycan assemble*

The peptidoglycan layer is a polymeric mesh of repeating units of N-acetylglucosamine (GlcNAc) and N-acetylmuramic acid (MurNAc) crosslinked by peptide “bridges.” This layer is believed to account for structural rigidity and, at the same time, allow certain fluidity necessary for the bacterial shape in various stages of growth and cell division (Nelson and Cox 2017). Many steps in the formation of the peptidoglycan layer at the different phases of its assembly are targets of inhibition by antimicrobials (see Figure 1.2).

The first phase of assembly occurs in the cytoplasm. Uridine diphosphate- (UDP) GlcNAc, which in turn is formed from fructose-6-P, is converted to UDP-MurNAc through the action of MurA and MurB. UDP-MurNAc is then converted to UDP-tripeptide through the action of the ligases MurC-E. Then, MurF adds the dipeptide D-Ala-D-Ala, which is in turn generated by D-Ala-D-Ala ligase, to form UDP-MurNac-pentapeptide. The second phase of the peptidoglycan assemble occurs at the inner face of the cytoplasmic membrane. Lipid I is formed by MraY

from UDP-MurNac-pentapeptide and the membrane-embedded bactoprenol-P. Subsequently, lipid II is formed with the addition of a GlcNAc moiety to lipid I, by MurG. The last step in this phase is the translocation of lipid II from the inner leaflet to the outer leaflet of the cytoplasmic membrane by the action of transmembrane flippases (Nelson and Cox 2017). The final phase occurs at the outer face of the cytoplasmic space, where transmembrane penicillin binding proteins (PBPs) with high molecular weight are located. These PBPs possess both a transglycosylase (TGase) and a transpeptidase (TPase) domain. The translocated lipid II meets with the catalytic TGase domain of PBPs, and its disaccharyl pentapeptide is transferred to the growing chain of peptidoglycan. The released bactoprenol-PP is recycled back to bactoprenol-P and flipped back to the inner face of the cytoplasmic membrane.

The TPase domain of the PBP is responsible for the cross-linking between glycan strands. In Gram-negative bacteria, TPases make a direct 3-4'-peptide cross bridge, resulting in the expulsion of a D-Ala as free amino acid (see Figure 1.2). In Gram-positive bacteria, TPases typically act on a pentaglycine-extended Lys residue, which comes from a modified lipid II (Lipid II 5xGly), generating longer and more flexible cross bridges in the peptidoglycan meshwork (Walsh and Wencewicz 2016).

A great variety of antibiotics target the formation of the peptidoglycan layer from the early steps until the cross-linking of the glycan strands (see Table 1.2). For example, the molecular basis of action of  $\beta$ -lactams is the long lifetime of acyl-enzyme intermediates (or penicilloyl enzymes) that they form with PBPs, particularly with the TPase domain. In a normal cycle, the life times of the natural acyl-enzyme intermediates are in the range of milliseconds, while the penicilloyl enzymes are stable for several hours (Walsh and Wencewicz 2016). The enzymes can no longer keep up with the demand for cross-linking new peptidoglycan strands. On the basis of the same molecular mechanism, some compounds target other types of PBPs responsible for  $\beta$ -lactam resistance:  $\beta$ -lactamases (see 1.2.2 Main resistance mechanisms). In therapeutics,  $\beta$ -lactamases inhibitors are used in combination with other  $\beta$ -lactams. Additionally, the TGase domain of PBPs is inhibited by the moenomycin family.

Figure 1.2 Peptidoglycan assembly in Gram-negative bacteria. Antibiotics targeting the peptidoglycan assembly and their molecular target are shown (blue). D-Ala: D-alanine, Ddl: D-alanine-D-alanine ligase, D-Glu: D-glutamic acid, GlcNAc: N-acetylglucosamine, L-Ala: L-alanine, L-Lys: L-lysine, MurA-G: enzymes involved in the biosynthesis steps of peptidoglycan within the cytoplasmic space, MurNAc: N-acetylmuramic acid, TGase: glycosyltransferase, TPase: transpeptidase. Adapted from Lovering et al. 2012 and Waksh & Wenczewicz 2016 (Lovering, Safadi, and Strynadka 2012; Walsh and Wenczewicz 2016)

Other compounds affect the biosynthesis of lipid II by inhibiting different steps in the formation of UPD-MurNAc-pentapeptide, such as phosphomycin, or by inhibiting MraY, such as tunicamycin. In addition to compounds that have enzymes as molecular targets, there are antibiotics that bind to the substrates of other enzymes. Such is the case of vancomycins and lantibiotics, which bind to lipid II and avoid the subsequent steps of peptidoglycan chain elongation. Other examples are friulimicin, which binds to bactoprenol-P, and bacitracin, which binds to bactoprenol-PP, affecting the bactoprenol recycling.

Table 1.2 Antibiotics targeting the peptidoglycan assembly

Mechanism	Example compounds
Acyl-enzyme intermediates with transpeptidases	Penicillins: ampicillin, carbenicillin, penicillin G, methicillin, piperacillin Cephalosporins: ceftazidime, cefazolin, ceftriaxone, ceftobiprole, ceftarolin Carbapenems: imipenem, meropenem, doripenem, faropenem, ertapenem Monobactams: aztreonam, BAL30072 $\beta$ -lactamases inhibitors: clavulanate, sulbactam, tazobactam
Inhibition of UDP-MurNAc-tripeptide and UDP-MurNAc-pentapeptide formation	Phosphomycin, 4-Thiazolides, feglymycin, sulfonamide, phosphinate, ATP analogs, D-cycloserine
Inhibition of MraY	Peptidyl nucleoside antibiotics: tunicamycin, mureidomycin, napsamycin, pacidamycin
Inhibition of transglycosylases/transpeptidases	Moenomycin, vancomycin
Sequestering of lipid II	Glycopeptides: vancomycin telavancin, teicoplanin, dalbavancin, oritavancin Lantibiotics: bacteriocin, nisin, lacticin 3147 Ramoplanin, lysobactin, mannopeptidomycin
Sequestering of bactoprenol-P and bactoprenol-PP	Friulimicin, amphomycin, tsuschimycin, Bacitracin

### 1.2.1.3 Blockade of protein synthesis

There is also a great variety of compounds that target the ribosomal bacterial protein synthesis. Those compounds affect different steps in any of the phases of the protein chain synthesis (see Figure 1.3).

First, in the initiation phase, the 30S and the 50S ribosomal subunits form a 70S complex together with m-RNA and the first of the aminoacyl-tRNA (aa-tRNA) in the peptidyl (P) site of the ribosome. Then, a second aa-tRNA is accommodated in the aminoacyl (A) site, with the assistance of the elongation factor Tu (EF-Tu). Chain elongation occurs with the amino acid of the first aa-tRNA is transferred to the second aa-tRNA, followed by a translocation of the resulting deacylated tRNA to the exit (E) site with the action of the elongation factor G (EF-G). Simultaneously, the translocation of the peptidyl-tRNA to the P site. In the elongation phase, the cycle from accommodation until translocation repeats itself until the mRNA has been translated, and the peptidyl chain is completed and liberated from the ribosome. The 30S and 50S subunits are uncoupled liberating the mRNA and starting the cycle again (see Figure 1.3).

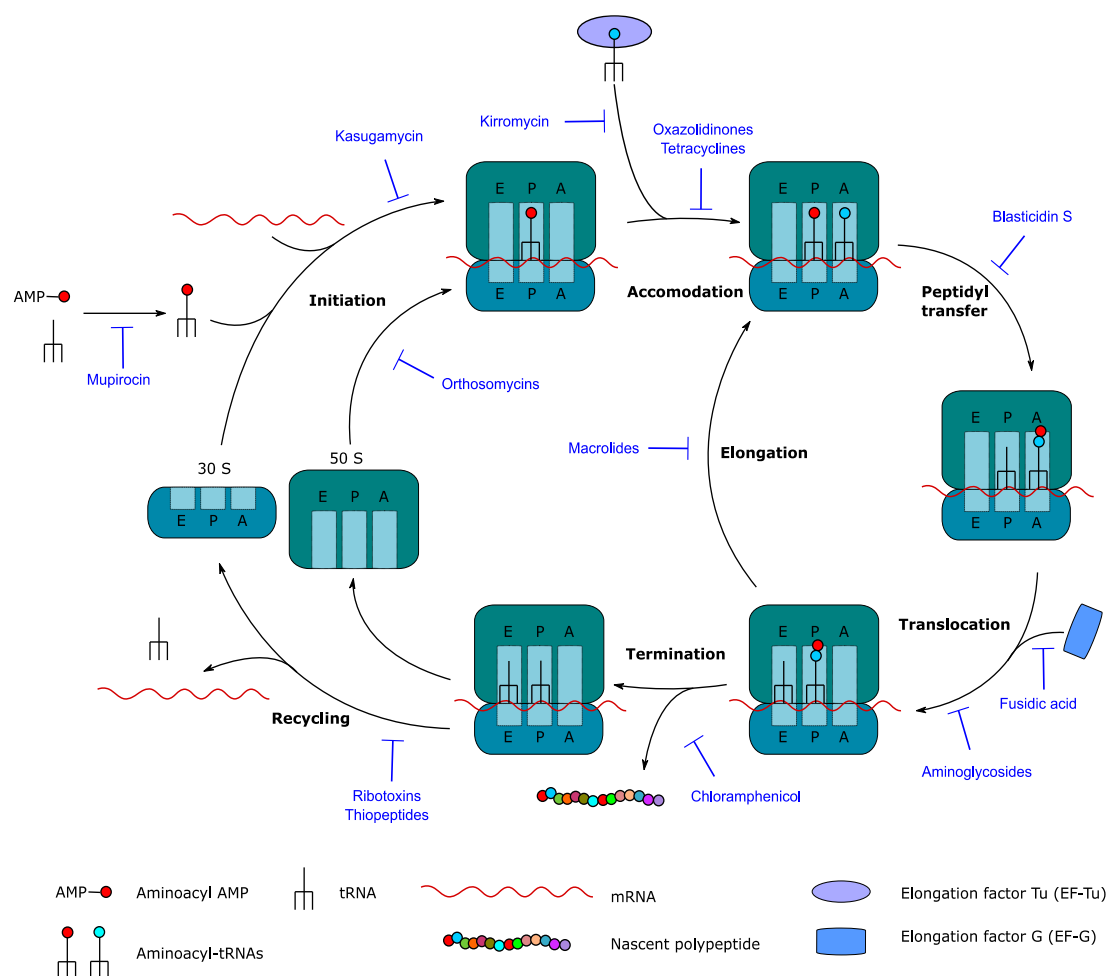

Figure 1.3 Bacterial protein synthesis. A: aminoacyl site, E: exit site, P: peptidyl site. Adapted from Wilson 2012, Arenz & Wilson 2016 and Walsh & Wencewicz 2016 (Arenz and Wilson 2016; Wilson 2013; Walsh and Wencewicz 2016)

Table 1.3 Antibiotics targeting the bacterial protein synthesis and their binding units

Target	Subunit	Example compounds
Ribosome	30S	Tetracyclines: tetracycline, minocycline, doxycycline, tigecycline
Ribosome	30S	Aminoglycosides: gentamycin, amikacin, tobramycin, kanamycin, streptomycin
Ribosome	30S	Kasugamycin, pactamycin, edeine A1
Ribosome	30S	Capreomycins: capreomycin IIA, viomycin
Ribosome / PTC	50S	Oxazolidinones: linezolid, puromycin
Ribosome / PTC	50S	Macrolides: erythromycin, chloramphenicol, telithromycin, tylosin, carbomycin
Ribosome / PTC	50S	Lincomycin, clindamycin, tiamulin, chloramphenicol
Ribosome / PTC	50S	Streptogramins A&B: dalfopristin and quinupristin (exit tunnel)
Ribosome	50S	Orthosomycins: everninomicin, avilamycin
Aminoacyl-tRNA synthetase	N.A.	Mupirocin, indolmycin, ochratoxin A, borrelidin, granaticin A, Cis-pentacin
EF-Tu	N.A.	Kirromycin, pulvomycin, GE2270A
EF-G	N.A.	Fusidic acid

N.A. Not applicable

### 1.2.1.4 Disruption of DNA and RNA information transfer

Unlike the large number and variety of antibiotics that target the bacterial ribosome, there are few compounds that selectively block the bacterial DNA and RNA information transfer. Bacteria have two sets of topo II enzymes, DNA gyrase, with subunits GyrA and GyrB, and topoisomerase IV, with subunits ParC and ParE. Gyrase regulates the supercoiling of double-stranded DNA (dsDNA) that occurs during DNA replication. When gyrase binds to the DNA, the two subunits each break one of the strands of dsDNA forming a covalently bound enzyme-substrate complex. After gyrase pulls the DNA through the cut site enabling topological relaxation, it reseals the two DNA strands before release.

Topoisomerase IV acts similar to DNA gyrase, although its major role seems to be the separation of two daughter chromosomal circles chain-like linked. Topoisomerase IV breaks one of the chromosomes and positions the cut side outside the second chromosome, then reseals the cut resulting in two separated chromosomes (Higgins 2007).

Fluoroquinolones, such as ciprofloxacin, target the GyrA subunit of DNA gyrase, forming tripartite complexes by stabilizing the covalently bound enzyme-substrate complex (see Figure 1.4). The inability to reseal the DNA strands leads eventually to cell death (Aldred, Kerns, and Osheroff 2014). Ciprofloxacin is the most active fluoroquinolone against *P. aeruginosa* (Campoli-Richards et al. 1988; T., BH., and PM. 2020)

Figure 1.4 Quinolone activity blocking the DNA information transfer. DNA helicase binds to the lagging-strand template at each replication fork and moves the replication fork breaking hydrogen bonds. DNA gyrase and topoisomerase IV relieves strain ahead of the replication fork. When DNA gyrase or topoisomerase IV are inhibited, the extra tension from supercoiling of DNA is not relieved, and the buildup of mechanical strength cause the DNA to break. Adapted from (Kohanski, Dwyer, and Collins 2010; Walsh and Wencewicz 2016)

On the other hand, some compounds, such as novobiocin, target GyrB subunit of gyrase (see Table 1.4) (East et al. 2009). Other antibiotics affect the activity of the bacterial RNA polymerase (RNAP). In general, these compounds bind to the RNAP interrupting the transcription of DNA into mRNA (see Table 1.4).

Table 1.4 Antibiotics targeting bacterial topoisomerases and RNA polymerase

Target	Subunit	Example compounds
DNA gyrase Topoisomerase IV	GyrA ParC	Fluoroquinolones: nalidixic acid, norfloxacin, ciprofloxacin, levofloxacin, lomefloxacin
DNA gyrase	GyrB	Clorobiocin, novobiocin, quinaoline, coumarins
RNA polymerase	N.A.	Rifamycin, rifampicin (rifampin), rifapentine, rifabutin Sorangicin Lipiarmycin (fidaxomycin) Myxopyronin B, crallopironin A, ripostatin A

N.A. Not applicable

#### 1.2.1.5 Blockade of the folate biosynthesis

As the folate coenzyme is biosynthesized in bacteria but not in humans, any reaction in the folate biosynthesis could be considered an antibiotic target (Pitt 2009). Compounds such as sulfonamide antibiotics, sulfamethoxazole, trimethoprim and abyssomicin C, block the folate pathway, resulting in a shutting off of bacterial DNA synthesis (Kompis, Islam, and Then 2005). Such antibiotics have a slow antimicrobial activity and are considered bacteriostatic.

### 1.2.2 Main resistance mechanisms

#### 1.2.2.1 Reduction in antibiotic uptake

Gram-negative bacteria are inherently more resistant to many classes of antibiotics than Gram-positive bacteria due to the additional permeability barrier conferred by their OM. Some even more resistant strains have the ability to regulate the entry and accumulation of antibiotics by altering their entry porins or activating their efflux pump machinery (see Figure 1.5). These organisms can alter the OM permeability either by controlling the size and number of their protein porins. For instance, uropathogenic *E. coli* expresses mutated versions of OmpC, reducing the permeability of  $\beta$ -lactams and fluoroquinolones (Lou et al. 2011). Similarly, *Pseudomonas* strains can limit the influx of carbapenems by producing fewer OprD porins, narrower pores or OM without any embedded porins (Fernández and Hancock 2012).

Figure 1.5 Resistance by alteration of porin proteins and activation of efflux pumps

In addition, Gram-negative possess three-protein pump machinery that spans all three components of their cell envelope, or tripartite transenvelope pumps, since they have to pump antibiotics out across two membranes (Opperman and Nguyen 2015; Tegos et al. 2011). Typically, Gram-negative bacteria express multi-drug resistance efflux pumps belonging to the resistance-nodulation-division (RND) family, the major facilitator superfamily (MFS) and the ATP-binding cassette (ABC) superfamily (Sun, Deng, and Yan 2014). These pumps use coupled proton motive force as the source of energy required for pumping out antibiotics against a concentration gradient. Unlike the RNS family, that exports a wide variety of compounds, the ABS superfamily exports macrolides out of the cells, while the MFS exports nalidixic acid and novobiocin (Pidcock 2006).

Particularly, *Pseudomonas aeruginosa* (*P. aeruginosa*) has high levels of constitutive and inducible expression of RNS tripartite transenvelope pumps. Most commonly found in *P. aeruginosa* are the constitutively expressed MexAB-OprM and MexXYOprM, and the inducible MexCD-OprJ, MexEF-OprN, and MexJK-OprM (Masuda et al. 2000). These efflux systems have the ability to export a great variety of antibiotics (see Table 1.5) (Fernández and Hancock 2012).

Table 1.5 Multi-drug efflux systems in *P. aeruginosa*

Efflux system	Example compounds
MexAB-OprM	Aminoglycosides, $\beta$ -lactams, chloramphenicol, macrolides, novobiocin, tetracyclines, trimethoprim
MexCD-OprJ	Chloramphenicol, cationic peptides, fluoroquinolones, tetracyclines
MexEF-OprN	Chloramphenicol, fluoroquinolones
MexJK-OprM	Aminoglycosides, fluoroquinolones, macrolides, tetracyclines
MexXYOprM	Aminoglycosides, fluoroquinolones, macrolides, tetracyclines

### 1.2.2.2 Modification of the compound

Some resistant bacteria have developed the ability of chemically modifying certain antibiotics, causing them to lose their antimicrobial activity. A classic example of enzymatic modification of antibiotics is the neutralization of  $\beta$ -lactams (Abraham and Chain 1940).

$\beta$ -lactamases are enzymes with an active site for  $\beta$ -lactams, like PBPs, but with a faster deacylation kinetics. Lactamases decompose the penicilloyl-enzyme intermediate by rapid hydrolytic deacylation, releasing a deactivated, ring-opened penicilloyl and the regeneration of the lactamase active site. There are four classes of  $\beta$ -lactamases, from A to D, and thousands of variants known. Another example of compound modification by ring-opening is the inactivation of the polyketide quinupristin and related streptogramins, where the macrocyclic ring is acetylated (Rende-Fournier et al. 1993).

Aminoglycosides also suffer deactivation by enzymatic activity. Aminoglycosides can undergo O-adenylation, O-phosphorylation or N-acetylation, or a combination of them (Llano-Sotelo et al. 2002).

### 1.2.2.3 Modification of the target

Point mutations in genes encoding antibiotic targets, often only by a single base, lead to a change in one amino acid in the encoded protein without affecting essentially its cellular function. Thus, the compound-target interaction is prevented and the uninhibited mutant target maintains its cellular function (see Figure 1.6).

Figure 1.6 Resistance by modification of the molecular target

One type of target modification is given by alterations in protein- and rRNA- encoding genes. Examples of alterations in protein-encoding genes are single nucleotide polymorphisms (SNPs) in GyrA, and in ParC, making the resistant strains less susceptible to fluoroquinolones

(Bruchmann et al. 2013). Another example is novobiocin producers, which often have mutations in GyrB that allow safe antibiotic production. Likewise, point mutations in the rpoB-encoded  $\beta$  subunit of RNAP provide resistance to rifamycins (Ovchinnikov et al. 1983). Trimethoprim resistance is commonly given by dihydrofolate reductase variants due to structural gene mutations (Bergmann et al. 2014).

Similarly, mutations in the 16S and 23S subunits of rRNA, given by alterations in the rRNA-encoding genes, confer resistance to kanamycin and apramycin to *M. tuberculosis*. Streptomycin producers also have protective mutations proximal to the anticodon-codon decoding site in the 30S subunit.

Another type of target modification is given by post-translational methylations of rRNA. The introduction of a methyl group into rRNA is likely to cause minimal perturbation but provides enough disturbance to small ligands, such as antibiotics. Post-translational methylations of rRNA are achieved via 16S rRNA methylases, which modify the small rRNA in the 30S subunit, and via 23S rRNA methylases, which modify the 23S rRNA before incorporation into the 50S subunit.

Aminoglycoside producers make use of methylation of the 16S subunit decoding site. Transferable plasmids have been found in clinical isolates of *P. aeruginosa* and *Klebsiella pneumoniae*. Macrolide producers are capable of methylating the PTC of the 50S subunit, blocking the binding of macrolides, lincosamides, and streptogramin B. Similar methyltransferases have been found in macrolide-resistant strains (Fyfe et al. 2016).

The third type of target modification occurs when bacteria change the net negative charge of the OM by enzymatic acylation or glycosylation of cell envelope components with positively charged amino groups. An example of that is the resistance to polymyxins in Gram-negative bacteria, where the LPS components of the OM are modified by the introduction of either one of two cationic groups, a 4-amino-L-arabinose or a phosphoethanolamine group. As a result, the introduced cationic group provides electrostatic repulsion of cationic antibiotics (Olaitan, Morand, and Rolain 2014).

Similarly, some Gram-positive bacteria increase the expression of the mprf (multiple peptide resistance factors) genes, induced by many cationic peptides, such as lantibiotic nisin, cationic aminoglycosides and by host antimicrobial defensins (Ernst et al. 2009). MprF produces lysyl-phosphatidylglycerols (lysinylation), reaching up to 40% of the total phosphatidylglycerols. As a result, lysinylation covers up to one phosphate negative charge with two positive ones, causing resistance to cationic peptides and to daptomycin. In the same

way, glycopeptide resistance (e.g., to vancomycin) is achieved by remodeling the pentapeptide end of lipid II. Five contiguous genes *vanRSHAX* are responsible for the substitution of the D-Ala-D-Ala moiety of lipid II by a D-Ala-D-lactate, decreasing the binding affinity of vancomycin (Walsh et al. 1996).

Finally, methicillin-resistant *S. aureus* (MRSA) strains have achieved to replace the susceptible PBP by a resistant one: PBP2a, with a lower affinity for methicillin, cephalosporins, and carbapenems (Stapleton and Taylor 2002). PBP2a has a half-life for acylation between 3-12 min in comparison with milliseconds required to form penicilloyl-PBPs.

### 1.3 Antibiotic uptake in Gram-negative bacteria

Overcoming the permeability barrier of Gram-negative bacteria poses a major challenge in the current era of antibiotic development. Attempts to better predict antibiotic uptake are currently gaining popularity in preclinical studies, and so the need to fully understand drug permeability and, even more, antibiotic uptake (Stavenger and Winterhalter 2014; Cama, Henney, and Winterhalter 2019).

Many studies over the last decades have described different methods to evaluate the accumulation of antibiotics in whole bacterial cells (see Table 1.6). Some methods rely on the indirect detection of the compound of interest, e.g. by determining the residual activity of the supernatant of a culture treated with antibiotic, or measuring the expression of a compound-inducible protein by its enzymatic activity (Chopra, Shales, and Ball 1982; Chopra and Hacker 1992). Another example of indirect detection is to monitor the degradation of a blue starch-iodine complex that reacts with the hydrolyzed form of  $\beta$ -lactams, leading to a discoloration of the solution (Zimmermann and Rosselet 1977). The hydrolyzed  $\beta$ -lactam is produced by the activity of  $\beta$ -lactamases forming a penicilloic acid.

Many other methods used in accumulation studies make use of a labeled form of the compound of interest, relying on the detection of radioactive incorporation or fluorescent probes (McMurry and Levy 1978; McMurry, Petrucci, and Levy 1980). Additionally, some fluorogenic probes that exhibit their fluorescence only by their activation through a protein expressed intracellularly provide uptake-specificity (Ferreira et al. 2017). Other, more direct methods detect the intrinsic fluorescence of the original compounds upon their spectrum of excitation and emission (Stone et al. 2019). Most importantly, the direct detection of unlabeled and unmodified compounds is achievable by LC-MS/MS methods.

In recent years, LC-MS/MS-based methods have been successfully applied in uptake studies because of their broad applicability and versatility. Their sensitivity allows for the absolute quantification of compounds in the pmol range, and they have been even used as cross-validation of other methods (Dumont et al. 2018). According to Zgurskaya and Rybenkov, LC-MS/MS could probably be considered the gold standard in efflux and permeation studies at the present (Zgurskaya and Rybenkov 2020).

Table 1.6 Methods used for the determination of antibiotic uptake in whole bacterial cells

Method	Description	Reference
Enzymatic activity	Monitoring the enzymatic activity of tetracycline-inducible $\beta$ -galactosidase	(Chopra, Shales, and Ball 1982; Chopra and Hacker 1992)
Fluorescence	Autofluorescent compound is directly monitored	(Samra, Krausz-Steinmetz, and Sompolinsky 1978; Leive et al. 1984; Chapman and Georgopapadakou 1988; McCaffrey et al. 1992; Li, Zhang, and Nikaïdo 2004; Bensikaddour et al. 2008; Cai et al. 2009; Coldham et al. 2010; Kaščáková et al. 2012; Meylan et al. 2017)
Fluorophore	The compound of interest is conjugated to a fluorescent dye, and the fluorescence is monitored	(Benincasa et al. 2009; Ning et al. 2011; Phetsang et al. 2016; Ferreira et al. 2017; Allam et al. 2017)
Fluorogenic dye	Bacteria express a fluorescence activator protein, while the compound of interest is conjugated to a fluorogenic dye	(Ferreira et al. 2017; Stone et al. 2019)
LC-MS/MS	Monitoring the chromatographic signal of the compound of interest, which is detected by a mass spectrometer	(Liu et al. 2003; Schumacher et al. 2006; Cai et al. 2009; Bhat et al. 2013; Davis, Gerry, and Tan 2014; Zhou et al. 2015; Richter et al. 2017; Dumont et al. 2018; Graef et al. 2018; Iyer et al. 2018; Prochnow et al. 2018; Wang et al. 2018; Spangler et al. 2018)
MALDI-MS/MS	The sample is adsorbed in a solid matrix while a projected beam ionizes the compound of interest to be detected by a mass spectrometer	(Tian et al. 2017)
Photometry	The hydrolyzed product of $\beta$ -lactams is stoichiometrically oxidized by iodine. The degradation of a blue starch-iodine complex is reflected by discoloration of the solution.	(Zimmermann and Rosselet 1977; Malouin et al. 1991; Lei et al. 1991; Kojima and Nikaïdo 2013)
Radiometry	The compound of interest is modified with a radioactive label. The incorporation of radioactivity is monitored.	(McMurry and Levy 1978; McMurry, Petrucci, and Levy 1980; McMurry, Cullinane, and Levy 1982; Gutmann et al. 1985; Hooper et al. 1989; Bedard et al. 1989; Diver, Piddock, and Wise 1990; Mortimer and Piddock 1991; Li, Livermore, and Nikaïdo 1994; Williams and Piddock 1998; Williams, Chung, and Piddock 1998; Oethinger et al. 2000; Li, Zhang, and Nikaïdo 2004; Hasdemir et al. 2004; Cai et al. 2009; Krishnamoorthy et al. 2016)
Residual activity	Determine the antimicrobial activity of the supernatant of a treated culture	(Celesk and Robillard 1989; Bazile et al. 1992; Walters et al. 2003)
Spectrofluorimetry	The compound of interest is monitored within a range of excitation and emission wavelengths	(Chopra, Shales, and Ball 1982; Piddock and Zhu 1991; Piddock et al. 1999; Ricci and Piddock 2003; Cinquin et al. 2015; Vergalli et al. 2017; Vergalli et al. 2018; Westfall et al. 2017; Siriyong et al. 2017; Dumont et al. 2018)

## 1.4 Bacterial adaptation to antibiotics

The massive and indiscriminate use of antibiotics in humans, animals, aquaculture, and agriculture is the most important component in the development of antibiotic resistance (Carlet et al. 2012). When cycled across different environments, antibiotics concentration gradients exert selective pressure on bacteria, leading to the selection of resistant strains, which also transmit to different environments and mobilize resistant genes and determinants (Andersson and Hughes 2014).

In infections, pathogens adapt to their host's defenses by coping with diverse stresses such as oxidative, acidic, osmotic, temperature, nutrient starvation, and antibiotic stress. All these stresses can impact antibiotic susceptibility (Poole 2012). Additionally, when antibiotic concentrations in body fluids and tissues are lower than the lethal concentrations, bacterial growth is inhibited, but the totality of the cells is not killed, and the infection can resume later (Felden and Cattoir 2018). Efforts in understanding the mechanisms of how pathogens interact with antimicrobial drugs and how they ultimately develop resistance highlight the microbial interaction to sub-lethal levels of those compounds (Andersson and Hughes 2014; Bernier and Surette 2013; Davies, Spiegelman, and Yim 2006; Gullberg et al. 2011; Linares et al. 2006).

### 1.4.1 Metabolomics approach on the effects of antibiotics in bacteria

A growing body of evidence shows that exposing bacteria to antibiotics induces a specific metabolic response according to the antibiotic's mode of action. This has enabled the prediction of the mode of action of unknown compounds by comparing bacterial metabolic responses to those generated after exposure to reference antibiotics. This approach has been applied in different strains such as *S. aureus*, *E. coli*, and *M. smegmatis* (Dörries, Schlueter, and Lalk 2014; Vincent et al. 2016; Zampieri et al. 2018; Yang et al. 2019), and even in *S. cerevisiae* treated with diverse antifungal compounds (Allen et al. 2004) (see Table 1.7).

Table 1.7 Recent studies on the mode of action of antibiotics

Compounds	Strain	Analytical method	Overview	Reference
Ciprofloxacin, erythromycin, fosfomicin, ampicillin, vancomycin	<i>S. aureus</i>	<sup>1</sup> H-NMR, GC-MS/MS, LC-MS/MS	Antibiotic dependent metabolic regulation	(Dörries, Schlueter, and Lalk 2014)
AZ1, fosmidomycin, AZ7, Triclosan, CCCP, Ceftazidime, CHIR-090, 2-(cyclobutylmethoxy)-5'-deoxyadenosine	<i>E. coli</i>	LC-MS/MS	Prediction of MOA	(Vincent et al. 2016)
Ampicillin, carbenicillin, doxycycline, kanamycin, streptomycin, tetracycline, cephalacin, ciprofloxacin, ofloxacin	<i>E. coli</i>	<sup>1</sup> H NMR	Prediction of MOA	(Hoerr et al. 2016)
Kanamycin, spectinomycin, hydrogen peroxide, chloramphenicol, amoxicillin, ampicillin, norfloxacin, nalidixic acid, trimethoprim, sulfamethizole	<i>E. coli</i>	MS and MS/MS direct injection	Responsive metabolites: specific to antibiotic, specific to MOA, and promiscuous	(Zampieri et al. 2017)
62 compounds with known MOA 212 new antimycobacterial compounds	<i>M. segmantis</i>	MS and MS/MS direct injection	Prediction of MOA	(Zampieri et al. 2018)
Ampicillin, ciprofloxacin, gentamycin	<i>E. coli</i>	LC-MS/MS	Prediction of MOA	(Yang et al. 2019)

Although it is well accepted that antibiotics have diverse and specific mechanisms of action, some authors suggest that antibiotics kill bacteria by rather a general mechanism. Antibiotics of different classes with distinct targets are proposed to affect the balance in bacterial metabolism, respiration and iron homeostasis, which leads to an increase in the production of oxidants and radicals, and eventually to bacterial cell death (Dwyer et al. 2014). Reactive oxygen species (ROS) have been found to be generated by hyperactivation of bacterial metabolism and to be important for killing bacteria (Kohanski et al. 2007; Dwyer et al. 2012; Dwyer et al. 2014; Lobritz et al. 2015). Conversely, low levels of ROS induced by sub-inhibitory antibiotic concentrations have a strong influence on the promotion of resistance (Kohanski, DePristo, and Collins 2010).

The elevated antibiotic-induced oxidative stress resulting from disruptions in the cell wall, protein synthesis, and DNA metabolism may propitiate a metabolic imbalance, as well as perturbations in respiration and iron homeostasis (Dwyer et al. 2014). The open question remains on whether bacterial redox imbalance could predict new classes of bactericidal antibiotics, whereas the killing effect of antibiotics goes beyond growth inhibition (Walsh and Wenczewicz 2016).

However, cell death as a result of antibiotic treatment is difficult to study due to the diverse cellular mechanisms involved, such as gene expression, growth control, programmed cell death, biofilm formation, and generation of traits involved in resistance as well as in persistence (Van Acker and Coenye 2017). The implication of self-induced cell death as a programmed response to stressful conditions has been extensively studied (Aldsworth, Sharman, and Dodd 1999; Rice and Bayles 2003; Engelberg-Kulka et al. 2006). Antibiotic-induced self-disintegration has also been shown in *P. aeruginosa* (Häussler and Becker 2008).

#### 1.4.2 Sub-lethal concentrations of antibiotics

Diverse studies have found that bacteria respond readily to antibiotics, even when they are exposed to sub-lethal and even sub-inhibitory concentrations, by the analysis of gene expression and mutation rate (Goh et al. 2002; Ishikawa and Horii 2005; Verbrugghe et al. 2016; Kohanski, DePristo, and Collins 2010; Karatuna and Yagci 2010; Breidenstein, Bains, and Hancock 2012; George and Halami 2017) , proteomic studies (Xiong et al. 2017; Jedrey, Lilley, and Welch 2018), as well as metabolomics studies (Phelan, Fang, and Dorrestein 2015; Han et al. 2019).

In many cases, exposure to insufficiently lethal concentrations of antibiotics has conferred bacteria, such as *P. aeruginosa*, with resistance and persistence traits to different antibiotics, mostly by modulating the expression of many genes related with efflux pumps, cell envelope and enzyme production (Breidenstein, de la Fuente-Núñez, and Hancock 2011).

Additionally, there is evidence that bacteria undergo metabolic shifts as an adaptation response when encountering novel environments (Martínez-Solano et al. 2008; Behrends et al. 2013), conferring bacteria with antibiotic resistance. For instance, *P. aeruginosa*'s sensitivity to aminoglycosides can be enhanced by inducing a metabolic shift in the central carbon metabolism (Allison, Brynildsen, and Collins 2011; Meylan et al. 2017). This underlines the important relation between the bacterial metabolism and the antibiotic susceptibility

## 1.5 Metabolome analysis

### 1.5.1 Introduction to metabolomics

Over the past decades, the “omics” techniques have been exploited in systems biology applications. Systems biology is the study of complex interactions in biological systems, evaluating the effect of external factors on the genome (genomics), the transcriptome (transcriptomics), the proteome (proteomics) and the metabolome (metabolomics) (see Figure 1.7) (Horgan and Kenny 2011). Very often, an integrated analysis of these “omics” is required to understand the complex function of a large number of different cellular responses.

Figure 1.7 “Omics” technologies and the “omes”. Genome is the complete nucleotide sequence in the genetic material of a living cell. Transcriptome is the complete set of all mRNA present in the cell. Proteome is the complete set of all proteins present in the cell. Metabolome is the complete set of all metabolites in the cell. Fluxome is the complete set of all fluxes through the different biochemical pathways. Adapted from Vilas-Bôas et al. 2006 (Villas-Bôas et al. 2007)

Particularly, metabolomics is the systematic characterization of the metabolome under very specific conditions (see Table 1.8). Thus, metabolomics involves various steps, from the design of experiment, sampling, sample preparation, sample analysis to data analysis (Dettmer, Aronov, and Hammock 2007). Sampling preparation often brings high variability in the metabolome analysis, and it is highly organism-dependent. A very important step in sample preparation is the rapid quenching of the biochemical processes at the sampling time, as metabolic concentrations change very rapidly under any variation (even unnoticed variations) (Villas-Bôas et al. 2007).

Table 1.8 Basic concepts in metabolomics

Concept	Definition
Metabolism	The sum of all the chemical transformations within a cell or organism
Metabolite	An intermediate or end product in biosynthetic and degradative pathways
Metabolic pathway	A series of enzyme-catalyzed reactions
Metabolome	The complete collection of metabolites produced or used within a cell
Endometabolome	The subset of intracellular metabolites
Exometabolome	The subset of metabolites excreted into the extracellular medium
Metabolomics	An approach to analyzing the metabolome or a fraction of the metabolome
Metabolic fingerprint	Analysis of the endometabolome
Metabolic footprint	Analysis of the exometabolome
Metabolite profiling	Analysis of a group of specific metabolites
Untargeted metabolite analysis	Global analysis of the metabolome (comprehensive)
Targeted metabolite analysis	Analysis of a subset of the metabolome (validation)

Sample preparation for metabolomics studies in microorganisms often requires several steps after quenching the metabolism, including the separation of the biomass from the extracellular medium, extraction of the endometabolome, conditioning the sample before its chemical analysis. The analysis of the metabolome covers the detection and identification of all (or most) intracellular and extracellular small molecules (with molecular mass under 1000 Da), and different analytical techniques are commonly used.

The complexity of the metabolome is so large that it is not possible to detect the complete collection of metabolites in one analysis. For example, metabolic fingerprint and footprint are often analyzed by mass spectrometry (MS), nuclear magnetic resonance spectrometry (NMR), or infrared spectroscopy (IR). In metabolite profiling, as many known and unknown metabolites as possible are detected, and is usually done by chromatography or capillary electrophoresis (CE) in combination with MS. On the other hand, target analyses intend to detect and quantify specific metabolites, and a large number of analytical techniques are available.

MS-based metabolomics allows for quantitative analysis with high sensitivity and the potential to identify metabolites. MS, in combination with a separation technique, such as liquid chromatography (LC) or gas chromatography (GC), provides more information on the physical-chemical properties of the metabolites.

### 1.5.2 Mass spectrometry and liquid chromatography

Mass spectrometry is a destructive analytical technique that allows for the determination of the nominal mass of an analyte. MS does not directly determine the mass of an analyte, but the mass-to-charge ratio ( $m/z$ ) of the ions originating from the analyte. One fundamental requirement of mass spectrometers is that the ions must be in the gas phase before they can be detected according to their individual  $m/z$  values (Watson and Sparkman 2007).

Among a number of ionization techniques electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) have been predominantly used in the analysis of biological samples, where very often the analytes are thermally labile and nonvolatile (Watson and Sparkman 2007). In ESI, a liquid solution containing the analyte is sprayed at the tip of a metal nozzle maintained at a positive potential (positive mode) or at a negative potential (negative mode). The nozzle disperses the solution into a fine spray, while a dry gas at atmospheric pressure reduces the size of the droplets by solvent evaporation (see Figure 1.8).

Figure 1.8 Electrospray ionization (ESI) in positive mode Adapted from (Siuzdak 2003). The solution passes through a positively charged nozzle where small, charged droplets are formed and they are dried by applying heat and cross-directional flow of gas. As evaporation occurs, positive charges are concentrated in even smaller droplets, creating an ionic repulsion among the ions of interest before they enter to the mass analyzer. A gas curtain helps minimizing the entry of solvent molecules and neutral species to the mass analyzer (Kang, Schneider, and Covey 2017)

ESI is known for producing singly charged small molecules, and frequently multiply charged species in larger molecules (Siuzdak 2003). In addition to protonation, adduct formation with sodium, potassium and ammonium takes place in the charged nanodroplets produced in positive-mode ESI (Gao, Zhang, and Karnes 2005; Cech and Enke 2001). The resulting charged molecules are the molecular ions to be detected according to their  $m/z$  values. In a tandem MS analysis, or MS/MS, different molecular ions are selected and separated, and fragment ions are generated in a collision cell from each molecular ion, or precursor ion (see Figure 1.9). In MS/MS mode, fragments originated from the precursor ion often provide structural information.

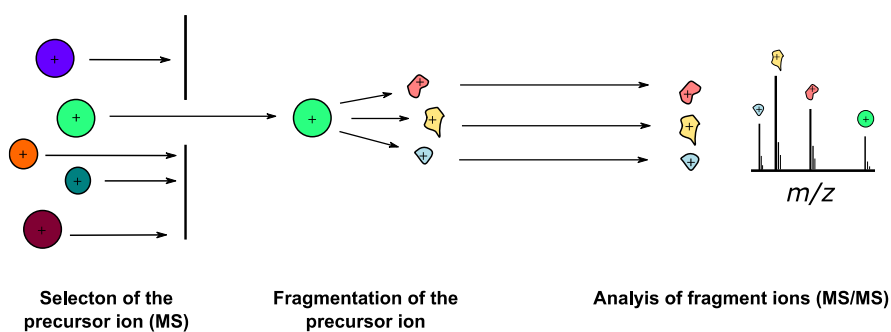

Figure 1.9 Tandem mass spectrometry Adapted from (Siuzdak 2003). The molecular ion of interest is selected according to its  $m/z$  value and separated to undergo fragmentation in a collision cell. The generated fragments, and the rest of the precursor ion are detected by the mass analyzer

Due to their good to excellent accuracy, good resolution and high sensitivity, the most commonly used mass analyzers in tandem MS are quadrupoles, time-of-flight (ToF) and Fourier-Transform Mass Spectrometry (FTMS) connected in series (Siuzdak 2003). For instance, in triple quadrupoles, the first quadrupole (Q1) scans across an  $m/z$  range and selects an ion of interest. The second quadrupole (Q2) serves a collision cell, fragmenting the selected ion along its flight path, while the third quadrupole (Q3) analyzes the fragment ions generated in Q2 (see Figure 1.10). Similarly, in a Q-ToF, the quadrupole selects the ion of interest, and sends it to a collision cell for fragmentation. The resulting fragments travel through an accelerating potential, where the lighter ions reach the detector first, while the heavier ions take longer to reach (see Figure 1.11.).

Tandem MS analyzers are often coupled to a chromatographic separation unit, as good separation of analytes reduces background noise, leading to improved detection limits and data quality (Dettmer, Aronov, and Hammock 2007). Reversed phase (RP) liquid chromatography is widely used in metabolomics analysis, as it is a standard tool for separating medium polar and non-polar metabolites. The applicability of LC-MS/MS has gained ground in the analysis of biological samples in the last decades (Pitt 2009).

Figure 1.10. Configuration of a triple quadrupole (QQQ). The ions that were produced in the source enter through orifice in the curtain plate, and they are transferred through an ion guide that creates a barrier against neutral molecules and micro droplets. Similarly, an also quadrupole array, Q0, transmits the ions to the first mass resolving quadrupole, Q1. In Q1, the precursor ion of interest is selected by adjusting the ratio of radio frequency (RF) and direct current (DC), RF/DC, so that only one particular  $m/z$  ratio have a stable trajectory through the quadrupole. The selected precursor ion undergoes fragmentation in Q2, or collision cell, and the fragments are monitored in the third quadrupole, Q3, which is connected to a continuous electron multiplier as detector. Adapted from (AB Sciex 2015).

Figure 1.11. Configuration of a quadrupole time-of-flight (Q-TOF) ions are generated in the source chamber, and transferred through the hexapole unit up to the quadrupole. In MS mode, there is not ion isolation in the quadrupole and the collision cell operates at low collision energy. In MS/MS mode, the precursor ion of interest is isolates in the quadrupole and sent to the collision cell operating at high collision energy for collision-induced dissociation (CID). The ion fragments are accelerated into a flight path, required for the calculation of the velocity of the ions (heavier ions with the same charge reach lower speeds). A reflectron helps ions with the same  $m/z$  but different kinetic energies reach the detector at the same time (less energetic ions penetrate less profound into the reflectron, taking a shorter path to the detector). Adapted from (Bruker Daltonics 2012)

### 1.5.3 Data analysis in metabolomics

Raw data in LC-MS/MS analysis come in the shape of chromatographic peaks with different intensities, where each chromatographic peak is the sum of the intensity of all molecular ions eluting at a particular retention time (RT). In MS level, or MS<sup>1</sup>, a mass spectrum is generated, while in MS/MS, or MS<sup>2</sup>, each of the precursor ions with a defined m/z value contains information of its fragment ions.

Noise filtering, peak detection, peak deconvolution and retention time alignment are required to identify features, which are pairs with an m/z value, a retention time and, if it is the case, MS/MS information. It is important to note that a feature is not always a metabolite, as related species (e.g. isotopes, adducts or multiply charged ions) of a single metabolite may be present with different m/z values (Schrimpe-Rutledge et al. 2016). Thus, one single chemical species may generate different features in an LC-MS/MS analysis. Similarly, the annotation of isotopic peaks corresponding to a particular molecular ion and its fragment peaks is also required (Cambiaghi, Ferrario, and Masseroli 2016; Dettmer, Aronov, and Hammock 2007).

Metabolite identification remains a big challenge in untargeted metabolomics (Creek et al. 2014). Usually, *in-house* compound libraries are used for the direct comparison of mass spectra to assign metabolite identity to a feature. Apart from that, there are different open databases available such as Human Metabolome Database (HMDB), the Metabolite and Tandem MS Database (METLIN), and organism-specific databases such as the *E. coli* Metabolome Database (ECMDB) or the recent *Pseudomonas aeruginosa* Metabolome Database (PAMDB) (Wishart et al. 2017; Guijas et al. 2018; Guo et al. 2013; Huang et al. 2018).

## 1.6 *Pseudomonas aeruginosa* as a model organism

*P. aeruginosa* is a Gram-negative aerobic bacillus that causes severe hospital-acquired infections, especially in immunocompromised hosts (Lyczak, Cannon, and Pier 2000). Among other infections, *P. aeruginosa* causes bacteremia in severe burn victims, chronic lung infections in cystic fibrosis patients, and acute ulcerative keratitis in patients with serious eye disorders (Lyczak, Cannon, and Pier 2000). To worsen the situation, *P. aeruginosa*'s clinical isolates are often antibiotic resistant, hampering the choice of therapy, and they are often associated with a high mortality rate and high hospitalization burden (WHO 2017).

*P. aeruginosa* exhibits high intrinsic resistance to a wide variety of compounds, such as aminoglycosides,  $\beta$ -lactams, and aminoglycosides. This broad antibiotic resistance is given by low outer membrane permeability,  $\beta$ -lactamase production, efflux pump overexpression, target mutations and the expression of regulatory genes (Behrends et al. 2013; Chalmers 2017; Subedi et al. 2018; Breidenstein, de la Fuente-Núñez, and Hancock 2011; Fraile-Ribot et al. 2017). Antibiotic resistance has been related to bacterial virulence, as virulence genes are often influenced by conditions found in the host environment and help the bacteria to cope with the encountered stresses (Breidenstein, de la Fuente-Núñez, and Hancock 2011).

Some examples of virulence factors are secreted molecules such as elastases, proteases, phospholipase C, hydrogen cyanide, exotoxin A, exoenzyme S, phenazines and rhamnolipids. Other associated factors, like flagella, pili, and LPS also contribute to the pathogenesis of *P. aeruginosa* (Cornelis 2008). Virulence factors in *P. aeruginosa* are known to be regulated by a complex network of quorum sensing (QS) small molecules, also called autoinducers, which serve to regulate gene expression (Moradali, Ghods, and Rehm 2017; Nadal Jimenez et al. 2012; Cornelis 2008). Furthermore, *P. aeruginosa* strains are known to be highly virulent, particularly PA14 is more virulent than PAO1 (Lee et al. 2006).

QS is controlled by an interconnected regulatory network that initiates by the cumulative production of autoinducers in a cell-density dependent manner and results in collective responses (see Figure 1.12). Three linked QS systems, Las, Rhl, and PQS (Pseudomonas Quorum Sensing) rule the production of many of *P. aeruginosa* virulence factors. Las and Rhl systems use N-acyl-homoserine lactones as signal molecules, where the Las system controls the Rhl system. The PQS system has also a hierarchical dependence on Las, and it involves the production of 2-heptyl-3-hydroxy-4-quinolone. Phenazines, such as pyocyanin, depend on the Rhl and the PQS systems. While the production of rhamnolipids is known to be controlled by the Rhl system (Nadal Jimenez et al. 2012; Moradali, Ghods, and Rehm 2017).

Figure 1.12 Quorum sensing regulatory circuits for *P. aeruginosa*'s virulence factors. *P. aeruginosa* responds to stress and stimuli, producing autoinducers C4-HSL, 3-oxo-C12-HSL, PQS. Export and import of HSL are mediated by the action of the efflux pumps MexAB-OprM and MexEF-OprN. BHL is import and export are achieved by diffusion. PQS translocation is mediated by membrane vesicles. Transcriptional factors LasR, RhIR, and PqsR are activated by autoinducers to upregulate the expression of their synthases, LasI, RhII and PqsABCDH, respectively. Other virulence factors are overexpressed as well, and their secretion is mediated by type1 and type 2 secretion systems, PvdRT-OpmQ efflux pump as well as simple diffusion. 3-oxo-C12-HSL: 3-oxo-C12-homoserine lactone, AprA: alkaline protease, C4-HSL: N-butylhomoserine lactone, HCN: hydrogen cyanide, LasA: LasA elastase, LasB: LasB elastase, Lec A: lectin A, PLC: phospholipase C, PQS: 2-heptyl-3-hydroxy-4-quinolone. Pvd: pyoverdine, Pyo: pyocyanin, Rha: rhamnolipids, ToxA: toxin A. Adapted from Moradali *et al.* 2017 and Cornelis 2020 (Moradali, Ghods, and Rehm 2017; Cornelis 2020)

Phenazines are virulence factors with antibiotic activity, as they trigger the formation of reactive oxygen species (ROS), although they also have antifungal and antiparasitic activities (Guttenberger, Blankenfeldt, and Breinbauer 2017). Phenazines have been related to biofilms, as they can maintain the redox homeostasis where oxygen exchange can be compromised (Price-Whelan, Dietrich, and Newman 2007; Guttenberger, Blankenfeldt, and Breinbauer 2017).

Biofilm formation is a major burden in antimicrobial therapy since a biofilm offers physical protection that protects bacteria from adverse environmental conditions (Wu, Cheng, and Cheng 2019). For instance, antibiotic amounts in biofilms can be reduced to sub-lethal concentrations, which can lead to antibiotic resistance (Lebeaux, Ghigo, and Beloin 2014).

Conversely, the overproduction of rhamnolipids inhibits biofilm formation (Davey, Caiazza, and O'Toole 2003). Although the biological function of rhamnolipids is still unclear, rhamnolipids seem to enhance the initial adherence of cells to a surface (Al-Tahhan et al. 2000), and the uptake of hydrophobic compounds (Noordman and Janssen 2002).

## **2. AIM OF THE DISSERTATION**

As noted before, pathogenic bacteria have the ability to cope with a wide variety of environmental stress, and they adapt to their host cell's environment. To accomplish this, bacteria rely on the rapid modification of metabolism and gene expression. The knowledge of how modifications on gene expression provide bacteria with antibiotic resistance has been widely documented, and the understanding of how these alterations influence bacterial responses at the metabolic level is on the rise. However, the knowledge of how metabolism promotes resistance and how it influences the activity of antibiotics and is still limited. herefore, the aim of this study was to obtain a comprehensive picture of the metabolism of *P. aeruginosa* upon antibiotic stress under limited lethality via untargeted analysis based on ultra-performance liquid chromatography and mass spectrometry. First, an evaluation on the metabolic fingerprint of *P. aeruginosa* upon sub-lethal concentrations of selected antibiotics was carried out in order to discern whether with different modes of action exhibit distinctive metabolic responses.

Although there is a body of evidence that shows how bacterial responses to antibiotics depend strongly on the encountered concentrations, little is known on how strongly such responses depend in the exposure times to the antibiotic-induced stress. Hence, one of the aims of this study was to evaluate *P. aeruginosa*'s response to clinically relevant antibiotics classes under short and long exposure times, under the same cultivation conditions.

Furthermore, there are still unknown aspects of the off-target mechanisms that antibiotics exert in bacteria. Since the relation between the degree of accumulation of a compound and its consequent effects on the bacterial response has not been extensively investigated, this study aimed to collect information on the indirect effects of ciprofloxacin in *P. aeruginosa* by comparing the metabolic fingerprints of a susceptible and a resistant strain showing similar compound accumulation. Ultimately, this study aimed to uncover the off-target effects of ciprofloxacin in a *P. aeruginosa* strain with a reduced drug-target interaction.

Additionally, a part of this study was devoted to developing a robust and strain-transferable plate-based assay for the quantification of antibiotic uptake, with the potential to be used in a high-throughput accumulation screening workflow of known and novel compounds. As starting point, the optimization of experimental settings and minimization of the handling volumes were contemplated. One of the ultimate goals of such a development was to measure the amounts of accumulated antibiotic in different strains, most emphatically in Gram-negative bacteria such as *E. coli* and *P. aeruginosa*, and to show the accumulation profiles of a selection of antibiotics in such organisms.

### 3. MATERIALS AND METHODS

#### 3.1 Materials

##### 3.1.1 Strains

Table 3.1 List of strains used in this study

Strain	Information	Reference
<i>E. coli</i> K-12 MG1655	Wild type, N.S.M.	(Blattner et al. 1997)
<i>P. aeruginosa</i> UCBPP-PA14	Human isolate, N.S.M.	(Rahme et al. 1995)
PA14 <i>gyrA</i> Thr83Ile	PA14, <i>gyrA</i> Thr83Ile, N.S.M.	(Bruchmann et al. 2013)
PA14 <i>gyrA</i> Thr83Ile <i>parC</i> Ser87Leu	PA14, <i>gyrA</i> Thr83Ile <i>parC</i> Ser87Leu, N.S.M.	(Bruchmann et al. 2013)

N.S.M.: No selection marker

##### 3.1.2 Chemicals

Table 3.2 List of chemicals used in this study

Name	Company
Ammonium sulfate ((NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> )	Sigma-Aldrich
Azithromycin	Sigma-Aldrich
Caffeine	Sigma-Aldrich
Casaminoacids (CasAA)	Roth
Ciprofloxacin	Sigma-Aldrich
Clarithromycin	Sigma-aldrich
Clindamycin	Cayman Chemical Company.
Erythromycin	Sigma-Aldrich
Fosfomycin	Sigma-Aldrich
Gentamycin	Sigma-Aldrich
Glipizide	Acros
Glucose monohydrate	Roth
Iron(II) sulfate (Fe <sup>(II)</sup> SO <sub>4</sub> )	Sigma-Aldrich
Levofloxacin	Sigma-Aldrich
Lomefloxacin	Sigma-Aldrich
Lyncomycin	Sigma-Aldrich
Meropenem	Sigma-Aldrich
Magnesium chloride hexahydrate (MgCl <sub>2</sub> ·6H <sub>2</sub> O)	MP Biomedicals
Magnesium sulfate heptahydrate (MgSO <sub>4</sub> ·7H <sub>2</sub> O)	Roth
Nalidixic acid	Cayman Chemical Company
(S)-Naproxene	Cayman Chemical Company
Nortriptyline	Sigma-Aldrich
Novobiocin	Sigma-Aldrich
Potassium phosphate dibasic (K <sub>2</sub> HPO <sub>4</sub> )	Merck
Potassium dihydrogen phosphate (KH <sub>2</sub> PO <sub>4</sub> )	Merck
Sodium phosphate dibasic (Na <sub>2</sub> HPO <sub>4</sub> )	Roth
Sodium dihydrogen phosphate (NaH <sub>2</sub> PO <sub>4</sub> )	Roth
Streptomycin	Sigma-Aldrich
Sulfamethazole	Fluka Analyticals
Tetracycline	Sigma-Aldrich
Tigecycline	LKT Labs
Tobramycin sulfate	Fluka Analyticals
Trimethoprim	Sigma-Aldrich

## 3.1.3 Equipment and consumables

Table 3.3 List of equipment and consumables used in this study

<b>Name</b>	<b>Company</b>
AB Sciex QTrap 6500 ESI-QQQ	AB Sciex Germany GmbH, Darmstadt, Germany
AcroPrep™ Supor® 96-well filter plate, 2 mL, 0.45 µm pore size	Pall Corporation, NY, USA
Agilent 1290 UHPLC	Agilent Technologies, Santa Clara, CA, USA
Bravo Automated Liquid-Handling Platform	Agilent Technologies, Santa Clara, CA, USA
Centrifugal vacuum concentrator	Labconco Corporation, Kansas, MO, USA
Centrifugation tube filters 0.2 µm Corning® Costar® SPIN-X®	Corning Inc., NY, USA
ChemiDoc XRS	BioRad, Hercules, CA, USA
Cold trap at -50°C	Labconco Corporation, Kansas, MO, USA
Conical bottom receiver plate, 350-µL, clear polypropylene	Greiner Bio-One GmbH, Frickenhausen, Germany
Deep-well rounded-bottom plate, 1 mL	NUNC, Denmark
Dionex Ultimate 3000 UPLC	Thermo Fisher Scientific, Waltham, MA
Eppendorf tubes® 1 mL, 2 mL, and 5 mL	Eppendorf AG, Hamburg, Germany
Falcon™ tubes	Corning Inc., NY, USA
Image Lab software	BioRad, Hercules, CA, USA
Kinetex C18 reverse phase column with 1.7 µm particle size and 2.1 mm	Phenomenex, Aschaffenburg, Germany
maXis™ HD QTOF	Bruker, Bremen, Germany
microtiter plates clear PP, flat bottom, untreated,	NUNC, Denmark
Millipore SteriCup® filter cups	Merck KGaA, Darmstadt, Germany
MultiScreenHTS DV filter plate, transparent, 300 µL, 0.45 µm pore size	Merck Millipore, Tullagreen, IRL
Parafilm plastic foil	Bemis CompanyInc, USA
PH meter	Mettler-Toledo, Switzerland
Plate adapter	Self-made
Plate reader	BioTek Instruments, Winooski, Vermont, USA
Square plates with lid, 12cm x 12cm	Greiner Bio-One GmbH, Frickenhausen, Germany
ThermoMixer® C	Eppendorf GmbH, Hamburg, Germany
ZORBAX Eclipse Plus C18 reverse-phase column 2.1 x 5.0 mm, 1.8 µm	Agilent Technologies, Santa Clara, CA, USA

## 3.1.4 Preparation of diverse solutions

## 3.1.4.1 BM2 medium

Basal Medium 2 (BM2) complemented with 0.01% casaminoacids (CasAA) was freshly prepared for every experiment according to Table 3.4. Every stock was prepared separately and sterilized by filtration through Millipore SteriCup® filter cups, and a 10x concentrated BM2 buffer autoclaved (Table 3.5).

Table 3.4 Stock dilution and medium preparation

Stock solution	Sterilization	Dilution	Final concentration of compound	Volume to prepare 1L of medium (mL)
10x BM2	Autoclaved	1:10	1 x BM2	100
20% (w/v) Glucose	steril filtered	1:50	0.4% Glucose	20
1 M MgSO <sub>4</sub>	steril filtered	1:500	2 mM MgSO <sub>4</sub>	2
10 mM FeSO <sub>4</sub>	steril filtered	1:1000	10 µm FeSO <sub>4</sub>	1
2,5% (w/v) CasAA	steril filtered	1:250	0.01% CAA	4
Milli-Q® filtered water	steril filtered	N.A.	N.A	873

Table 3.5 BM2 preparation

Compound	Final concentration (M)	Molar mass (g/mol)	Amount for 500 mL of stock (g)
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	0.07	132.14	4.62
K <sub>2</sub> HPO <sub>4</sub>	0.4	174.18	34.83
KH <sub>2</sub> PO <sub>4</sub>	0.22	136.09	14.97
Milli-Q® filtered water	N.A	N.A.	445.58

#### 3.1.4.2 NaPi-MgCl<sub>2</sub> buffer

100 mM NaPi buffer + 5 mM MgCl<sub>2</sub> buffer for uptake assay was prepared according to Table 3.6. The pH was adjusted with NaOH solution to reach 7.0 before adjusting the final volume with filtered water. The whole solution was sterilized by filtration through Millipore SteriCup® filter cups.

Table 3.6 Preparation of NaPi buffer for uptake assay (100 mM NaPi buffer + 5 mM MgCl<sub>2</sub>)

Stock solution	Sterilization	Dilution	Final concentration of compound	Volume to prepare 500 mL of buffer (mL)
1 M NaH <sub>2</sub> PO <sub>4</sub>	steril filtered	1:20	50 mM NaH <sub>2</sub> PO <sub>4</sub>	21.1
1 M Na <sub>2</sub> HPO <sub>4</sub>	steril filtered	1:20	50 mM Na <sub>2</sub> HPO <sub>4</sub>	28.9
500 mM MgCl <sub>2</sub>	Autoclaved	1:100	5 mM MgCl <sub>2</sub>	5
1 N NaOH	N.A.	N.A.	Until pH = 7.0	< 1 mL until pH = 7.0
Milli-Q® filtered water	steril filtered	N.A.	N.A	< 445

#### 3.1.4.3 Antibiotic solutions for uptake experiments

Stocks of antibiotics were prepared by dissolving 1 to 2 mg of compound in solvent according to Table 3.7 to reach a concentration of 1 mg/mL. Further dilutions were carried out with NaPi buffer to reach a final concentration of 1 mM. For uptake assays, 25 µL of antibiotic stock solutions was added to 100 µL of bacterial solution, so that the final concentration of compound was 200 µM.

Table 3.7 Preparation of 1 mM antibiotic stocks for uptake experiments in filter plates

Compound	Solvent for first dilution*	Molar mass (g/mol)	Stock mass concentration (mg/mL)	Stock molar concentration (mM)
Ciprofloxacin	First in 0.1 mL 0.1 N HCl, then dilution with NaPi	331.35	0.331	1
Clindamycin	NaPi	424.98	0.425	1
Phosphomycin	NaPi	182.02	0.182	1
Lyncomycin	NaPi	461.01	0.461	1
Nalidixic acid	First in 0.1 mL 0.1 N NaOH, then dilution with NaPi	232.24	0.232	1
Novobiocin	First in 0.1 mL 0.1 N HCl, then dilution with NaPi	634.61	0.635	1
Streptomycin	First in 0.2 mL H <sub>2</sub> O, then dilution with NaPi	728.69	0.729	1
Sulfamethazole	NaPi	253.28	0.253	1
Tetracycline	NaPi	480.90	0.481	1
Tigecycline	First in 0.2 mL H <sub>2</sub> O, then dilution with NaPi	585.65	0.586	1
Tobramycin	First in 0.2 mL H <sub>2</sub> O, then dilution with NaPi	467.51	0.468	1

\* Compounds were first dissolved to 1 mg/mL, then sterilized by filtration, and further dilutions were carried out with NaPi buffer

#### 3.1.4.4 Antibiotic solutions for metabolomics experiments

Stocks of antibiotics were prepared by dissolving 0.7 to 1.0 mg of compound in enough solvent to reach a concentration of 1 or 2 mg/mL, and they were sterilized by filtration through Spin-X® tube filters. Further dilutions were carried out with BM2 medium to reach the stock concentrations listed in Table 3.8. For metabolomics experiments in filter plates, 50 µL of antibiotic stock solutions was added to 1 mL of bacterial solution.

Table 3.8 Preparation of antibiotic stocks for metabolomics experiments in deep-well filter plates

Compound	Solvent for first dilution	Stock concentration (µg/mL)	Final concentration in 1.05 mL (µg/mL)
Azithromycin	First in 0.1 mL DMSO, then dilution with BM2 upto 2 mg/mL	1050	50
Ciprofloxacin	First in 0.1 mL 0.1 N HCl, then dilution with BM2 upto 1 mg/mL	4.2	0.2
Clarithromycin	First in 0.1 mL DMSO, then dilution with BM2 upto 2 mg/mL	1050	50
Erythromycin	First in 0.5 mL H <sub>2</sub> O, then dilution with BM2 upto 2 mg/mL	1050	50
Levofloxacin	First in 0.1 mL 0.1 N HCl, then dilution with BM2 upto 1 mg/mL	4.2	0.2
Lomefloxacin	First in 0.2 mL H <sub>2</sub> O, then dilution with BM2 upto 1 mg/mL	4.2	0.2
Meropenem	First in 0.2 mL H <sub>2</sub> O, then dilution with BM2 upto 1 mg/mL	210	10

For metabolomics experiments in test tubes, the stock solutions were prepared similarly. 50 µL of antibiotic stock solutions was added to 1 mL of bacterial solution, following the concentrations listed in Table 3.9.

Table 3.9 Preparation of antibiotic stocks for metabolomics experiments in test tubes

Compound	Solvent for first dilution	Stock concentration ( $\mu\text{g/mL}$ )	Final concentration in 3.1 mL ( $\mu\text{g/mL}$ )
Azithromycin	First in 0.1 mL DMSO, then dilution with BM2 to 2 mg/mL	124	4
Ciprofloxacin	First in 0.1 mL 0.1 N HCl, then dilution with BM2 to 1 mg/mL	1.55	0.05
Erythromycin	First in 0.5 mL H <sub>2</sub> O, then dilution with BM2 to 2 mg/mL	124	4
Gentamycin	First in 0.5 mL H <sub>2</sub> O, then dilution with BM2 to 1 mg/mL	6.2	0.2
Levofloxacin	First in 0.1 mL 0.1 N HCl, then dilution with BM2 to 1 mg/mL	1.55	0.05
Tobramycin	First in 0.5 mL H <sub>2</sub> O, then dilution with BM2 to 1 mg/mL	6.2	0.2

For metabolomics experiments upon sub-inhibitory concentrations of ciprofloxacin, the stock solutions were prepared from a common stock of ciprofloxacin at 1 mg/mL.

Table 3.10 Preparation of antibiotic stocks for metabolomics experiments in test tubes

Treatment	Stock concentration ( $\mu\text{g/mL}$ )	Final concentration in 3.1 mL ( $\mu\text{g/mL}$ )
Control	0.00	0.000
NIC	0.50	0.016
IC10	0.72	0.023
IC50	1.83	0.059
MIC	4.67	0.151

### 3.1.4.5 Internal standards

In addition, internal standards stocks (ISTDs) were prepared by solubilizing approx. 0.7 mg of compound in solvent according to Table 3.11.

Table 3.11 Preparation of internal standards stocks for metabolomics studies

Compound	Solvent	Stock concentrations	Dilution	Final concentration in 80% v/v MeOH
Trimethoprim	MeOH	0.1 mg/mL	1:1000	0.1 $\mu\text{g/mL}$
Nortriptyline	MeOH	0.1 mg/mL	1:1000	0.1 $\mu\text{g/mL}$
Glipizide	MeOH	0.1 mg/mL	1:1000	0.1 $\mu\text{g/mL}$
Naproxene	MeOH	0.1 mg/mL	1:100	1 $\mu\text{g/mL}$
Caffeine	MeOH	0.1 mg/mL	1:100	1 $\mu\text{g/mL}$

## 3.2 Microbiological methods

### 3.2.1 Determination of colony-forming units (CFUs)

Bacterial solutions were serially diluted in a microtiter plate. 100  $\mu\text{L}$  of the corresponding dilutions  $1:10^6$  and  $1:10^7$  were distributed in plain LB (Luria Bertani broth) agar plates and incubated at 37 °C for 24 h. CFUs were determined for the dilution that showed less than 100 colonies.

### 3.2.2 Spot-plating

For each sample of interest, 10  $\mu\text{L}$  was serially diluted in 90  $\mu\text{L}$  of PBS in a 96-well microtiter plate. From each well, 2  $\mu\text{L}$  were carefully dropped onto 12cm x 12cm square LB agar plates with a Bravo Automated Liquid-Handling Platform. The plates were incubated at 37°C for 24 h. Images were taken with a ChemiDoc XRS and processed with the Image Lab software.

### 3.2.3 Determination of inhibitory concentrations

Overnight cultures were prepared with 5 mL of BM2 + 0.01% CasAA inoculated with the corresponding strain and incubated overnight at 37 °C and 150 rpm. 20 mL of fresh BM2 were inoculated with 0.7 mL of overnight culture (starting  $\text{OD}_{600} \approx 0.1$ ) and incubated at 37 °C and 150 rpm until an  $\text{OD}_{600} = 1.0$  was reached. 1 mL culture was centrifuged in 2-mL Eppendorf tubes (9 min, 4500xg, 20°C) and the supernatant was discarded. The pellet was resuspended in fresh BM2 to reach an  $\text{OD}_{600} = 0.1$ . Compounds were first dissolved in water to reach 1 mg/mL (for ciprofloxacin, approx. 0.7 mg first dissolved in 100  $\mu\text{L}$  0.1 N HCl and further diluted in water), and further dilutions in BM2 were carried out to reach the required stock concentration. 100  $\mu\text{L}$  of stock solution (4  $\mu\text{g}/\text{mL}$  for ciprofloxacin) were given to the first column of a microtiter plate and 1:2 serial dilutions followed, leaving 50  $\mu\text{L}$  in each well. 50  $\mu\text{L}$  of bacterial solution were mixed in every well of the microtiter plate containing 50  $\mu\text{L}$  of antibiotic solution ( $\text{OD}_{600} = 0.05$ , max concentration 2  $\mu\text{g}/\text{mL}$ ). The plate was incubated at 37°C for 24 h and the  $\text{OD}_{600}$  was measured in a plate reader.  $\text{OD}_{600}$  values were analyzed with the R Shiny App (Ebner 2016) to determine the non-inhibitory concentration (NIC), the concentration at 10% growth loss (IC10), the concentration at 50% growth loss (IC50) and the minimum inhibitory concentration (MIC), where a Gompertz function is fitted to the data (sigmoid curve) (Lambert and Pearson 2000).

### 3.3 Targeted analysis for uptake quantification

#### 3.3.1 Medium throughput method

##### 3.3.1.1 Uptake assay in 96-well filter plates

Overnight cultures of *P. aeruginosa* or *E. coli* were prepared with 5 mL of LB medium inoculated with one-single colony of the corresponding strain from a day-old LB-agar plate, and incubated overnight at 37 °C and 150 rpm. 2 x 60 mL of fresh LB broth was inoculated with 1 mL of overnight culture and incubated at 37 °C and 150 rpm (starting OD<sub>600</sub> ≈ 0.1) until reaching an OD<sub>600</sub> = 1.0 for *P. aeruginosa*, or OD<sub>600</sub> = 0.6 for *E. coli*. The bacterial cultures were centrifuged in 50-mL Falcon® tubes (9 min, 4500 x g, 20°C), the supernatant was removed, and the pellet was resuspended in 5 mL NaPi buffer to be again centrifuged under the same conditions. The supernatant was discarded and the pellet was resuspended in enough warm NaPi buffer to reach OD<sub>600</sub> = 5.0. 100 µL of bacterial suspension was given per well into a MultiScreenHTS DV filter plate (transparent, pore size 0.45 µm) dampened with 2 µL NaPi buffer and the plate was incubated at 37°C for 5 min. At time points 0, 10, 20, 30, 40, 45, 48, and 50 min (which become 50, 40, 30, 20, 10, 5, 2 and 0 min incubation times, respectively), 25 µL of the respective antibiotic solution was added in the corresponding wells and mixed by pipetting three times up and down to give a final volume of 125 µL and a concentration of 200 µM. The filter plate was shaken at 350 rpm and 37°C in a ThermoMixer® C during antibiotic addition.

For the 50 min time point (0 min incubation time), 25 µL of antibiotic solution was added right before filtration. The incubation was stopped by fast removal of the supernatant with a vacuum manifold (~15s) and the cells were washed twice with 100 µL of ice-cold NaPi buffer with the help of a Bravo Automated Liquid-Handling Platform. After every filtration, the filter plate was pressed against absorbent paper to remove the remaining liquid. The filter plate was placed on top of a 350-µL conical bottom receiver plate, and the pellets were resuspended in 100 µL of ice-cold 80% methanol-water. After that, the suspension was incubated for 30 min at 25°C and 450 rpm while sealed with Parafilm® and closed with a plate lid. Following the incubation step, the filter plate was centrifuged at 2250 x g for 5 min and the filtrate was collected in the receiver plate.

The cell debris was further extracted by resuspension in 100 µL of ice-cold acetonitrile before it was incubated for 30 min at 25°C and 400 rpm. The filtrate was then collected by centrifugation at 2250 x g for 15 min and then followed by evaporation using a centrifugal vacuum concentrator at 20°C coupled to a cold trap at -50°C. The dry remnants were

reconstituted in 100  $\mu\text{L}$  of 50% acetonitrile-water containing 0.1% v/v formic acid and 10 ng/mL caffeine (for positive mode) and 50 ng/mL glipizide (for negative mode) as internal standards. The samples were subsequently measured with LC-MS/MS methods specific for each compound, where 1  $\mu\text{L}$  of sample was injected to an UPLC-ESI-QQQ.

### 3.3.1.2 Uptake assay in round-bottom 96-well plates

Overnight cultures of *P. aeruginosa* or *E. coli* were prepared with 5 mL of LB medium inoculated with one-single colony of the corresponding strain from a day-old LB-agar plate, and incubated overnight at 37 °C and 150 rpm. 2 x 60 mL of fresh LB broth was inoculated with 1 mL of overnight culture and incubated at 37 °C and 150 rpm (starting  $\text{OD}_{600} \approx 0.1$ ) until reaching an  $\text{OD}_{600} = 1.0$  for *P. aeruginosa*, or  $\text{OD}_{600} = 0.6$  for *E. coli*. The bacterial cultures were centrifuged in 50-mL Falcon® tubes (9 min, 4500xg, 20°C), the supernatant was removed, and the pellet was resuspended in 5 mL NaPi-MgCl<sub>2</sub> buffer to be again centrifuged under the same conditions. The supernatant was discarded and the pellet was resuspended in enough warm NaPi buffer to reach  $\text{OD}_{600} = 5.0$ . 600  $\mu\text{L}$  of bacterial solution were distributed in a 1-mL round-bottom plate, and 50  $\mu\text{L}$  of antibiotic solution were added at fixed times, and the plate was kept shaking at room temperature and 400 rpm. The plate was centrifuged at 2250 x g (maximum speed for the swinging-plate rotor centrifuge) and 4°C on a plate adapter to distribute the pellets closer to the wall than the bottom. With the help of a Bravo pipetting robot, the removal of the supernatant was carried out by introducing the tips from the opposite side of the wall to avoid disruption of the pellets. The bacterial pellets were washed once and centrifuged again for 15 min at 4°C to remove the supernatant. Right after, bacterial cells were disrupted with 200  $\mu\text{L}$  of ice-cold 80% v/v MeOH in H<sub>2</sub>O for 30 min at room temperature and 400 rpm, followed by a second extraction with 200  $\mu\text{L}$  of ice-cold ACN for 30 min (total volume = 400  $\mu\text{L}$ ).

To remove cell debris and precipitated proteins, the plate was centrifuged for 45 min at 4 °C, and 200  $\mu\text{L}$  of the supernatant was transferred to a clean, conical-bottom receiver plate. The solution was dried overnight in a centrifugal vacuum concentrator at 20°C coupled to a cold trap at -50°C. The remaining dried solids were reconstituted in 100  $\mu\text{L}$  of LC-MS compatible solution (ACN:H<sub>2</sub>O 1:1 + 0.1% v/v formic acid + 10 ng/mL of caffeine as internal standard) and analysed using the appropriate LC-MS/MS methods. The antibiotic concentration was calculated from standard curves.

## 3.3.2 LC-MS/MS compound-specific MRM methods

Multi-reaction monitoring methods (MRM) were developed for each of the analyzed compounds (see Table 3.12). The selected compounds were dissolved in MeOH to reach a concentration of 10 µg/mL and directly injected to an AB Sciex QTrap 6500 ESI-QQQ mass spectrometer at a constant flow rate of 10 or 20 µL/min.

Table 3.12 Optimized parameters of multi-reaction monitoring methods (MRM)

Compound	Retention time, RT (min)	Column temperature (°C)	Precursor ion m/z (Da)	Fragment ions m/z (Da)	Declustering potential, DP (V)	Entering potential, EP (V)	Collision energy, CE (V)	Cell exit potential, CXP (V)
Caffeine	2.14	30	195.116	138.1	66	10	27	10
				110.1	66	10	31	6
Ciprofloxacin	2.64	30	332.040	314.2	111	10	27	16
				231.2	111	10	49	12

Tobramycin	0.39	30	468.261	163.1	101	10	31	10
				324.3	101	10	19	24

A full scan in Q1 was performed to identify the molecular ion of each compound by manually optimizing the declustering potential (DP) in the orifice plate and keeping an entering potential (EP) of 10 V in positive mode, and -10 V in negative mode. The molecular ion (also precursor ion) was selected in the first quadrupole (Q1) for further ion fragmentation in the second quadrupole (Q2), and the resulting ions were scanned in the third quadrupole (Q3). To identify the two most abundant fragment ions, the collision energy (CE) and the cell exit potential (CXP) in Q2 were optimized for best sensitivity. The transition (Q1 → Q3) from the precursor ion to the first fragment ion is considered as the quantifier (used for calculations of peak area against concentration), and the transition to second fragment ion is considered as the qualifier (confirmation of the original analyte).

Samples and standard curves were injected (1  $\mu\text{L}$  per sample) to a ZORBAX Eclipse Plus C18 reverse-phase column on an Agilent 1290 UPLC. The corresponding ion transitions, two for each compound and two for the internal standard, were monitored simultaneously (4 transitions in total) in AB Sciex QTrap 6500 ESI-QQQ mass spectrometer. Each run was recorded over 6 min with a constant flow rate of 700  $\mu\text{L}/\text{min}$  and a gradient elution with eluent A (water with 0.1% v/v formic acid) and eluent B (acetonitrile with 0.1% v/v formic acid) as follows: 1% B for  $t = 0$  min to  $t = 0.3$  min, linear gradient from 1% B to 99% B from  $t = 0.1$  min to  $t = 6$  min, hold 99% B until  $t = 6.2$  min and linear gradient from 99% B to 1% B from  $t = 6.2$  min to  $t = 8$  min.

### 3.3.3 Standard curves for antibiotic quantification

Standard curves were obtained by measuring predefined concentrations of antibiotics (see *Appendix I. Standard curves for uptake studies* **Error! Reference source not found.**). The integrated peak area was then plotted over antibiotic concentration in  $\mu\text{M}$  or  $\text{ng}/\text{mL}$ , and a linear regression curve was performed by least squares regression. The amount of antibiotic in bacterial samples was determined on the basis of the regression curve and the sample volume (100  $\mu\text{L}$ ).

### 3.4 Untargeted metabolomics studies

#### 3.4.1 Preparation of overnight culture and working culture

For overnight culture, 20 mL of freshly prepared BM2 in a non-baffled 50-mL flask was inoculated with a PA14 WT single-colony from a day-old LB agar plate. The culture was incubated overnight at 37°C shaking at 150 rpm. Before the preparation of working cultures, 10 mL of the overnight culture was transferred to a 50-mL Falcon™ tube and centrifuged at 5000 x g for 5 min. The supernatant was discarded and the pellet was washed with 1 mL of medium, and centrifuged again. The final pellet was resuspended in 10 mL of fresh BM2 medium reaching an optical density between 2.0 and 3.0.

Working cultures were prepared by transferring the required volume of BM2 to a clean, non-baffled 250-mL flask and inoculating it with medium to reach an  $OD_{600} = 0.05$ . For example, to prepare 100 mL of working culture, 97.5 mL of BM2 medium was mixed with 2.5 mL of bacterial solution with an  $OD_{600} = 2.0$ .

#### 3.4.2 Metabolomics in deep-well filter plates

A non-baffled 250-mL flask containing 100 mL of working culture (initial  $OD_{600} = 0.05$ ) was incubated at 37°C at 150 rpm until an  $OD_{600} = 1.0$ . Rapidly, 1 mL of a working culture was transferred to every well of a 96-well filter plate previously incubated at 37°C and with the bottom sealed with Parafilm plastic foil. 50 µL of antibiotic stocks dissolved in BM2 (see Table 3.8) was added to each well and mixed by pipetting up and down. In total, each condition had 9 replicates, including untreated controls with no antibiotics, and blank samples without bacteria as listed in Table 3.13. Blank samples were prepared by adding 1.05 mL of clean BM2.

Table 3.13 Samples for metabolomics studies in deep-well plates

Sample	Treatment	Replicates for analysis
CON	Untreated	6
CIPRO	Ciprofloxacin	6
LEVO	Levofloxacin	6
LOME	Lomefloxacin	6
AZI	Azithromycin	6
ERY	Erythromycin	6
CLARI	Clarithromycin	6
MERO	Meropenem	6
BLK	No bacteria	3

The plate was covered with a plate lid and located on a plate shaker at 400 rpm and 37°C. After 2 hours of incubation, the plate was filtered onto a vacuum manifold until no liquid remained (~ 3 min). Supernatants are not recovered with this method. The bacterial cells were washed immediately in 200 µL of ice-cold 0.9% m/v NaCl with an automated pipetting robot. The filter plate was pressed onto absorbent paper after every filtration to remove the excess of solution. Before cell lysis, the plate was placed onto a 300-µL conical-bottom receiver plate and its borders were sealed with Parafim. Both plates were kept on ice at all times.

Cells were lysed by resuspending them in 200 µL of ice-cold extraction solution (80% v/v MeOH with 0.1 µg/mL trimethoprim, 0.1 µg/mL glipizide and 0.1 µg/mL nortriptyline, as internal standards) with the pipetting robot. The solution was further homogenized twice by shaking for 1 min at 600 rpm in a plate shaker, followed by 10 min sonication (100% intensity and 0°C) in an ice-cold water bath. To collect the extract, the plates were centrifuged at 2250 x g and 4°C for 20 min, the filter plate was discarded and the contents of the receiver plate were dried overnight in a centrifugal vacuum concentrator at 20°C coupled to a cold trap at -50°C. The remaining dried solids were reconstituted in 30 µL of LC-MS compatible solution (80% v/v MeOH with 1 µg/mL caffeine and 1 µg/mL naproxen, as internal standards), and the plate was centrifuged at 2250 x g and 4°C for 20 min. 25 µL was transferred to brown glass vials with inserts for LC-MS/MS untargeted analysis.

### 3.4.3 Metabolomics in test tubes

#### 3.4.3.1 Short and long exposure to antibiotic concentrations

Both short- and long-exposure treatments were carried out under the same experimental configuration (see Table 3.14). 150 mL of working culture with initial  $OD_{600} = 0.05$  was prepared in a non-baffled 250-mL flask. 3 mL of the working culture were transferred to 10-mL glass test tubes, previously labeled for short and long exposure. For the long-exposure samples, 100 µL of the antibiotic stocks dissolved in BM2 (see Table 3.9) were added to the test tubes in triplicates at an initial  $OD_{600} = 0.05$ . Immediately after, all the tubes were incubated in an inclined rack at  $\theta = 60^\circ$ , 150 rpm and 37°C indistinctively of the label. When an  $OD_{600} = 0.5$  was reached in the tubes labeled as short exposure, 100 µL of the antibiotic stocks dissolved in BM2 were added to the test tubes in triplicates. All the tubes continued shaking until an  $OD_{600} = 1.0$ . Untreated controls were prepared by incubating 3 mL of the working culture without addition of any solution. Blank samples were prepared by adding 3-mL of fresh BM2 medium to the tubes.

Table 3.14 Samples short and long exposure to antibiotics in test tubes

Sample	Treatment	Replicates for long exposure	Replicates for short exposure
CON	Untreated	3 for both long and short exposure	
CIPRO	Ciprofloxacin	3	3
LEVO	Levofloxacin	3	3
AZI	Azithromycin	3	3
ERY	Erythromycin	3	3
GENTA	Gentamycin	3	3
TOBRA	Tobramycin	3	3
BLK	No bacteria	3 for both long and short exposure	

### 3.4.3.2 Sub-inhibitory concentrations

For each strain, PA14 WT and PA14 gyrAparC, 100 mL of working culture with initial OD<sub>600</sub> = 0.05 was prepared in a non-baffled 250-mL flask. 3 mL of the working culture were transferred to 10-mL glass test tubes. 100 µL of the antibiotic stocks dissolved in BM2 were added to the test tubes at an initial OD<sub>600</sub> = 0.05 to reach the desired concentration (see Table 3.10). One blank sample for each antibiotic was generated by adding 3-mL of fresh BM2 medium to 3 tubes. All the tubes were incubated in an inclined rack at  $\theta = 60^\circ$ , 150 rpm and 37°C until an OD<sub>600</sub> = 1.0.

Table 3.15 Samples for metabolomics studies upon sub-inhibitory concentrations

Sample	Treatment	Replicates for PA14 WT	Replicates for PA14 gyrAparC
CON	Untreated	3	3
NIC	Non-inhibitory	3	3
IC10	10% inhibition	3	3
IC50	50% inhibition	3	3
MIC	No growth (in plates)	3	3
BLK	No bacteria	3	3

### 3.4.3.3 Harvest and storage

From every test tube, 2 mL of bacterial solution were transferred to 2-mL Eppendorf tubes, previously labeled and kept on an ice bath. The tubes were centrifuged at 9000 x g for 5 min at 4 °C, transporting them in an ice bath at all times. 1 mL of the supernatants was transferred to labeled, clean Eppendorf tubes and the rest was discarded. The supernatants were submerged in liquid nitrogen and stored at -70°C until needed. The pellets were washed once in 1 mL ice-cold 0.9% NaCl by adding the solution to the tube and vortexing for 1 min (maximum speed). Pipetting up and down was avoided, so that fractions of the pellet did not stick to the

tips. The tubes were centrifuged again (9000 x g, 5 min, 4°C), and the supernatant was discarded. The tubes containing the washed pellets were submerged in liquid nitrogen and stored at -70°C until needed for metabolite extraction.

#### *3.4.3.4 Intrametabolome extraction*

Cells were lysed by adding 1 mL of ice-cold extraction solution (80% v/v MeOH with 0.1 µg/mL trimethoprim, 0.1 µg/mL glipizide and 0.1 µg/mL nortriptyline, as internal standards) in every sample. Pipetting up and down was avoided, so that fractions of the pellet did not stick to the tips. The solution was further homogenized twice by vortexing for 1 min (maximum speed), followed by 10 min sonication (100% intensity and 0°C) in an ice-cold water bath.

The tubes were centrifuged at 9000 x g for 5 min at 4 °C, transporting them in an ice bath at all times. 900 µL from each tubes was transferred to labeled, clean Eppendorf tubes and the rest was discarded. The contents of the tubes were dried overnight in a centrifugal vacuum concentrator at 20°C coupled to a cold trap at -50°C. The remaining dried solids were reconstituted in 100 µL of LC-MS compatible solution (50% v/v ACN in water with 1 µg/mL caffeine and 1 µg/mL naproxen, as internal standards), and the tubes were centrifuged at 10000 x g, and 4°C for 20 min. 50 µL was transferred to brown glass vials with inserts for LC-MS/MS untargeted analysis.

#### *3.4.3.5 LC-MS/MS untargeted analysis*

Replicates were analyzed on a Dionex Ultimate 3000 UPLC using a 150 mm Kinetex C18 reverse phase column with 1.7 µm particle size and 2.1 mm inner diameter coupled to a maXis™ HD QTOF mass spectrometer.

Full scans (50–1500 Da) were recorded in positive mode ESI, data-dependent MS/MS was performed by collision-induced dissociation of the five most abundant ions. Each run was recorded over 30 min with a constant flow rate of 300 µL/min and a gradient elution with eluent A (water with 0.1% v/v formic acid) and eluent B (acetonitrile with 0.1% v/v formic acid) as follows: 1% B for t = 0 min to t =2 min, linear gradient from 1% B to 100% B from t = 2 min to t =20 min, hold 100% B until t = 25 min and linear gradient from 100% B to 1% B from t = 25 min to t = 30 min.

### 3.5 Data processing and analysis

#### 3.5.1 Uptake data

The analysis of chromatogram peaks from samples and standard curves was performed automatically in MultiQuant™ 2.0 for each MRM. Manual determination of the peak area was performed when required. The peak table was exported and the scatter plots for antibiotic uptake and dose-response curves were plotted in SigmaPlot 14.0.

#### 3.5.2 LC-MS/MS data processing with XCMS Online

Raw data in mzXML format were processed in positive mode and negative mode with XCMS Online for feature detection and retention time alignment across samples. XCMS Online built-in CAMERA algorithm was selected to annotate isotopic features and adducts formations, dimers, trimers, neutral losses (for the settings, refer to Table 3.16). The generated feature tables were further processed with R (3.6.1) in RStudio.

Table 3.16 XCMS Online settings for raw data processing

Description	Name	Value
Maximal tolerated m/z deviation in consecutive scans (parts per million)	ppm	8
Minimum chromatographic peak width (s)	minimum peak width	5
Maximum chromatographic peak width (s)	maximum peak width	25
Minimum difference in m/z for peaks with overlapping retention time	mzdiff	0.0155
Signal-to-noise threshold	Signal/Noise threshold	30
Peak integration method	Integration method	1 (Mexican hat filter)
Minimum number of peaks for retention of mass traces	prefilter peaks	3
Peak intensity threshold	prefilter intensity	400
Noise threshold	Noise filter	100
Step size for profile generation of raw data	profStep	1
Retention time deviation (s)	bw	20
Minimum fraction of samples necessary in a group for it to be a valid group	minfrac	0.4

### 3.5.3 LC-MS/MS data processing with XCMS R package

Raw data in mzXML format were processed with the R-package for XCMS, and a feature table with MS1 information was generated (for the settings, refer to Table 3.17).

Table 3.17 Parameters for raw data processing with R-based XCMS

Function	Parameter	Value

### 3.5.4 Feature table processing

#### 3.5.4.1 Isotope filtering

Feature filtering was carried out by refining isotopic ion peaks annotated by CAMERA from the feature list. The features with isotopic labels and their multiple charges were filtered out, i.e. [M+1]<sup>+</sup> to [M+4]<sup>+</sup>, [M+1]<sup>2+</sup> to [M+4]<sup>2+</sup>, and [M+1]<sup>3+</sup> to [M+4]<sup>3+</sup>. The resulting filtered feature table contained singly- and multiply-charged molecular ions [M], including dimers, trimers and multiple adduct formation, as well as not annotated isotopic ions.

#### 3.5.4.2 Retention time cutoff

Retention time (RT) cutoff was applied to filter features coming from the injection peak (first minute of each run) and features coming from the column washing (last 5 min of each run). Therefore, a filter of  $0.3 \leq RT \leq 28$  min was applied.

#### 3.5.4.3 Normalization by internal standards

Signal normalization by internal standards (ISTDs) in positive mode was applied by calculating two consecutive normalization factors, one for injection standards (caffeine and naproxen) and

the other for extraction standards (trimethoprim and glipizide, but not for nortriptyline as it is better ionized in negative mode). First, a normalization factor for caffeine and naproxen was calculated for each feature  $i$  (rows) with the formulas:

$$norm\_factor_{caffeine,i} = \frac{max\ intensity_{caffeine}}{intensity_i}$$

$$norm\_factor_{naproxen,i} = \frac{max\ intensity_{naproxen}}{intensity_i}$$

A normalization factor for the injection standards was calculated as follows:

$$norm\_injection_i = \frac{norm\_factor_{caffeine,i} + norm\_factor_{naproxen,i}}{2}$$

Then, the intensity matrix with  $n$  features and  $m$  samples was processed as follows, for every feature in  $i = 1$  to  $n$ , and sample in  $j = 1$  to  $m$ :

$$norm\_feature\ intensity_{i,j} = feature\ intensity_{i,j} * norm\_injection_i$$

Subsequently, a norm factor for trimethoprim, glipizide was calculated as follows:

$$norm\_factor_{trimethoprim,i} = \frac{max\ intensity_{trimethoprim}}{intensity_i}$$

$$norm\_factor_{glipizide,i} = \frac{max\ intensity_{glipizide}}{intensity_i}$$

And a normalization factor for the extraction standards was calculated as follows:

$$norm\_extraction_i = \frac{norm\_factor_{trimethoprim,i} + norm\_factor_{glipizide,i}}{2}$$

Finally, the intensity matrix with  $n$  features and  $m$  samples was processed as follows, for every feature in  $i = 1$  to  $n$ , and sample in  $j = 1$  to  $m$ :

$$norm\_feature\ intensity_{i,j} = feature\ intensity_{i,j} * norm\_extraction_i$$

#### 3.5.4.4 Normalization by optical density

Similarly, normalization by the OD<sub>600</sub> value at harvest of each sample  $j$  (columns) was performed for every strain as follows:

$$ODnorm\_factor_{strain,j} = \frac{max\ OD_{strain}}{OD_j}$$

Where  $max OD_{strain}$  is the maximum OD<sub>600</sub> value at harvest of the respective strain: WT or gyrAparC. The intensity matrix with  $n$  features and  $m$  samples was processed as follows, for every feature in  $i = 1$  to  $n$ , and sample in  $j = 1$  to  $m$ :

$$norm\_feature\ intensity_{i,j} = feature\ intensity_{i,j} * ODnorm\_factor_{strain,j}$$

#### 3.5.4.5 Quantile normalization

Only for the metabolomics experiments in filter plates, a quantile normalization was carried out by using function `normalizeBetweenArrays()` with the method “quantile” from the R package “limma”. The feature table used for quantile normalization was not subjected to any other precedent or subsequent normalization.

#### 3.5.4.6 Addition of an offset value

After signal normalization, the data were log<sub>2</sub> transformed. However, log<sub>2</sub> cannot be applied to zero values. Therefore, a value of 50 was added up to all the intensity values from  $n$  to  $m$ , as a rule of thumb. By increasing the offset to 50 total counts, the zero values were filled up, and the natural distribution of the data was not modified.

#### 3.5.4.7 Removal of internal standard intensities

After the previous steps of feature table processing were carried out, the intensities of all five features corresponding to the ISTDs were deleted from the feature table within the same R script. The rest of identified m/z adducts from the ISTDs were removed manually (see 3.5.5.5 Manual refinement).

#### 3.5.4.8 Fold change and p-value calculation

The mean values of the log<sub>2</sub>-transformed intensity were calculated for each sample group. For fold change calculation, the mean value of the untreated control samples was subtracted from each of the mean value of the remaining groups, so that a positive value is attributed to up-regulation and a negative value is attributed to down-regulation. For p-value calculation, pairwise comparisons between sample groups were performed through T-tests in R with the function `pairwise.t.test()`.

### 3.5.5 Feature identification

#### 3.5.5.1 MS/MS annotation

Bruker MetaboScape 4.0 was used to process raw data and generate an MS/MS identified feature table with the use of two *in-house* libraries, one specific for *P. aeruginosa* (with 45 entries) and a general one (with 559 entries), as well as commercial libraries such as LipidBlast (with 14048 entries) and MetaboBase (with 482025 entries). For this purpose, a bucket table in positive mode was generated from the raw data files of all the samples of the experiment (for settings, refer to Table 3.18).

The resulting bucket table was exported. To combine the newly generated bucket table with the preprocessed XCMS Online feature table, they were matched by retention time and  $m/z$ . Firstly, the values for maximum and minimum retention time and  $m/z$  values were calculated for every MetaboScape bucket  $k$ , using an  $m/z$  tolerance of  $\pm 8$  ppm, and a retention time constrain of  $\pm 25$  s:

$$\max m/z_k = (1 + ppm) * m/z_k$$

$$\min m/z_k = (1 - ppm) * m/z_k$$

$$\max RT_k = RT_k + 25$$

$$\min RT_k = RT_k - 25$$

Then, every row of the processed feature table  $i$  was compared against the maximum and minimum values of each MetaboScape feature  $k$ , and the MetaboScape identification label was copied to the feature table only when:

$$\min m/z_k \leq m/z_i \leq \max m/z_k$$

and

$$\min RT_k \leq RT_i \leq \max RT_k$$

### 3.5.5.2 Exact mass identification by XCMS Online

XCMS Online provides a preliminary feature identification by matching the exact mass of the feature table with a predefined database (*biosource*, see Table 3.16). As a result, a tentative match table is generated with  $m/z$  values, compound ID,  $m/z$  difference, matched adduct, and the corresponding pathway. This matching list contains several doubles, meaning that the same exact mass matched with more than one metabolite in the database.

The XCMS Online tentative matches were compared against the processed feature table fitting their exact masses. Firstly, the values for maximum and minimum  $m/z$  values were calculated for every tentative match  $l$ , using an  $m/z$  tolerance of  $\pm 8$  ppm:

$$\max m/z_l = (1 + ppm) * m/z_l$$

$$\min m/z_l = (1 - ppm) * m/z_l$$

Then, every row of the processed feature table  $i$  was compared against the maximum and minimum values of each tentative match  $l$ , and the tentative identification label was copied to the feature table only when:

$$\min m/z_l \leq m/z_i \leq \max m/z_l$$

Several matches in the tentative matching for the same feature  $i$  were expected. So the value with the lowest mass difference was preferred. For this reason, systematic manual validation of exact mass matching was later carried out for the features of interest.

### 3.5.5.3 Spectral similarity clustering with GNPS

Spectral similarity among the features was found via an online-based GNPS Molecular Networking tool. This tool detects sets of spectra from related molecules (molecular networks), even when the spectra themselves are not matched to any known compounds in the built-in libraries.

The mzXML files for the triplicates of WT\_CON, WT\_IC50, gyrAparC\_CON and parC\_IC50 were processed with the following parameters: precursor ion mass tolerance = 0.01 Da, and fragment ion mass tolerance = 0.05 Da. The option for filtering peaks in 50 Da was not applied. The rest of the settings were kept as default. The processed data was visualized with Cytoscape (3.7.2), and an identified feature table was obtained.

The GNPS features were matched against the processed feature table by retention time and exact mass. Firstly, the values for maximum and minimum retention time and  $m/z$  values were

calculated for every GNPS feature  $g$ , using an  $m/z$  tolerance of  $\pm 8$  ppm, and a retention time constrain of  $\pm 25$  s:

$$\max m/z_g = (1 + ppm) * m/z_g$$

$$\min m/z_g = (1 - ppm) * m/z_g$$

$$\max RT_g = RT_g + 25$$

$$\min RT_g = RT_g - 25$$

Then, every row of the processed feature table  $i$  was compared to the maximum and minimum values of each GNPS feature  $g$ , and the GNPS identification label was copied to the feature table only when:

$$\min m/z_g \leq m/z_i \leq \max m/z_g$$

and

$$\min RT_g \leq RT_i \leq \max RT_g$$

#### 3.5.5.4 Spectral similarity clustering with CluMSID

Spectral similarity was performed with the R package CluMSID. CluMSID computes the cosine distance among MS/MS spectra and determines the spectral similarity of features within one single sample. Therefore, a convenient pooled (gyrAparC\_CON or gyrAparC\_IC50) sample was used for the analysis.

The CluMSID features were matched against the processed feature table by retention time and exact mass. Firstly, the values for maximum and minimum retention time and  $m/z$  values were calculated for every CluMSID feature  $h$ , using an  $m/z$  tolerance of  $\pm 8$  ppm, and a retention time constraint of  $\pm 25$  s.

$$\max m/z_h = (1 + ppm) * m/z_h$$

$$\min m/z_h = (1 - ppm) * m/z_h$$

$$\max RT_h = RT_h + 25$$

$$\min RT_h = RT_h - 25$$

Then, every row of the processed feature table  $i$  was compared to the maximum and minimum values of each CluMSID feature  $h$ , and the CIMSID identification label was copied to the feature table only when:

$$\min m/z_h \leq m/z_i \leq \max m/z_h$$

and

$$\min RT_h \leq RT_i \leq \max RT_h$$

#### 3.5.5.5 Manual refinement

Manual identification refinement was performed to fully integrate the described identification tools. The exported MetaboScape feature table did not contain the MS/MS annotated adducts that were otherwise visible in MetaboScape software. Additionally, spectral data were visualized with Bruker Compass DataAnalysis 4.2, and theoretical isotope distributions for proposed sum formulas were simulated with Bruker Compass IsotopePattern.

### 3.5.6 Data visualization methods

#### 3.5.6.1 PCA

An eigendecomposition of the scaled and log<sub>2</sub>-transformed data was carried out by the function `prcomp()` in R. The scores (eigenvalues) of the first two principal components (eigenvectors) were projected for every sample in a PCA plot. The explained variance for each principal component is a measure that represents how much information (variance) can be attributed to each principal component.

#### 3.5.6.2 Correlation matrix and heat maps

The correlation matrix was generated by calculating the correlation of the scaled and log<sub>2</sub>-transformed data with `cor()` in R. For visualization purposes, the values of `1-cor()` were plotted instead of the correlation values.

#### 3.5.6.3 U-plots

The feature table was separated in WT samples and gyrAparC samples. For each new data set, a correlation test was performed with the function `cor.test()` in R by comparing every row against the corresponding to ciprofloxacin. The method used for the correlation test was

“*spearman*” and the data were previously center scaled. The correlation of each feature was plotted against their respective p-value. For visualization purposes, the p-values from the correlation test were log10-transformed.

#### *3.5.6.4 Bar plots and box plots*

Bar plots were generated in R Studio by plotting features with Spearman correlation higher than 0.5 and lower than -0.5. Box plots were also generated in R Studio. The significance with respect to the control samples was plotted on the top of each box plot as follows: \*\*\* for p-value  $\leq 0.001$ , \*\* for  $0.001 < \text{p-value} \leq 0.01$ , \* for  $0.01 < \text{p-value} \leq 0.05$ , no asterisk for p-value  $> 0.05$ .

## 4. ANTIBIOTIC UPTAKE

### 4.1 Medium-high throughput assay for antibiotic uptake

The present work describes the implementation of a medium-high throughput assay for the screening of compound accumulation in bacteria. In its current state, the assay is transferable to different strains, including Gram-negative bacteria, such as *P. aeruginosa* or *E. coli*, and Gram-positive bacteria, such as *S. aureus*.

Until recently, experimental setups in LC-MS/MS-based uptake studies have always been carried out in the common lab-scale of approx. 20-50 mL (Bhat et al. 2013; Heumann 2015). Some approaches have reduced the working volumes in order to handle more samples at a time (Schumacher et al. 2006; Richter et al. 2017; Prochnow et al. 2018; Iyer et al. 2018). Few studies have implemented higher throughput assays in this direction (Cai et al. 2009; Widya et al. 2019).

In order to increase the throughput of a previously described assay for ciprofloxacin (Heumann 2015), the working volumes were reduced from 20 mL to 100  $\mu$ L. Reducing working volumes of the bacterial solution implies that the amount of cells is also reduced, decreasing the signal of the compound after the workflow. Thus, cell density was necessarily increased to compensate for the miniaturization of the geometry (Figure 4.1).

Figure 4.1 Scheme of volume reduction needed to increase the throughput in the uptake assay

#### 4.1.1 Uptake assay in deep-well plates

In the first attempts to achieve a higher throughput assay, the configuration of a 96-well plate with a capacity of 1 mL per well was chosen. In brief, 600  $\mu\text{L}$  of bacterial solution at  $\text{OD}_{600} = 5.0$  was distributed in each well of the plate. Bacterial cells were incubated with antibiotics for 10 min before centrifugation and removal of supernatant with a pipetting robot. To remove the totality of the supernatant and to avoid pellet disruption, the plate was centrifuged onto an adapter to force the bacterial cells to pellet far from the well bottom and closer to the wall, so that the pipetting robot aspirates the supernatant from the opposite side of the well (Figure 4.2). The pellets were washed once with buffer and lysed with an organic solvent mixture, to extract the internalized compound. The solution was then further processed to measure the amount of accumulated compound (see 3.3.1.2 Uptake assay in round-bottom 96-well plates).

Figure 4.2 Plate adapter for the uptake assay in deep-well round-bottom plates. The plate is centrifuged onto the adapter at an angle of  $15^\circ$  in a bucket centrifuge

One limitation of this procedure is the extended centrifugation times to achieve stable bacterial pellets that are not easily disturbed when aspirating the supernatant. Several trials to reduce the centrifugation times were performed (from 10 to 5 min), but the pellets were partially disturbed with the pipetting robot even at low aspiration speeds ( $100 \mu\text{L}/\text{min}$ ), or by decanting the contents of the plate upside down and removing the excess of liquid with absorbent paper.

The optimal centrifugation time was 15 min for *E. coli*, and 25 min for *P. aeruginosa*, resulting in dead times of 30 to 50 min before the extraction of the internalized compound. Therefore, the time-resolved accumulation of compounds during the first minutes of the incubation is not possible to determine.

In principle, the protocol in deep-well plates allows for the determination of the steady-state concentration of the accumulated compound. However, some results in  $\beta$ -lactam accumulation

show that the measured accumulation after 10 min incubation was lower than the proposed control at 0 min before centrifugation (Figure 4.3). This is an indication that, for some compounds, the concept of steady-state concentration might not hold true.

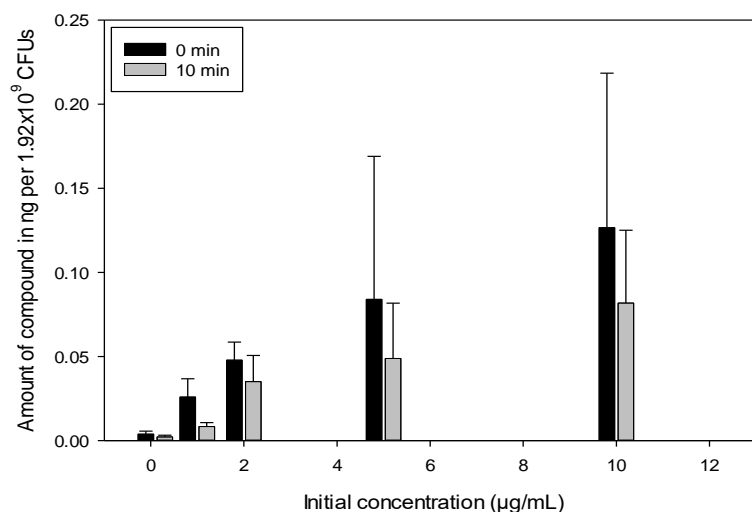

Figure 4.3 Meropenem uptake in *E. coli* BW25113 wild type after 0 and 10 min incubation at 37°C in NaPi buffer, and washed once with Napi buffer (2x15 min centrifugation at 2250 rpm and 4°C). The bars represent the average values of the three replicates and the standard deviation is represented with the error bars

Although this protocol allows the observation of the steady-state concentration of antibiotics, it will not be useful for time-resolved assays. Thus, a filter plate assay was developed for depicting time-course accumulation profiles.

#### 4.1.2 Uptake assay in filter plates

In order to improve the dead times in the uptake assay, a workflow optimized for filter plates was developed. In brief, 100 µL of bacterial solution at  $OD_{600} = 5.0$  was distributed in each well of the filter plate. Antibiotic solutions were added at different time points, and the incubation was stopped by the fast filtration of the solution (~15 s). The filtered bacteria were washed twice with fresh buffer with a pipetting robot. To extract the internalized compound, the pellets were lysed with an organic solvent mixture. The solution was then further processed to measure the amount of accumulated compound (see 3.3.1.1 Uptake assay in 96-well filter plates).

## 4.1.2.1 Selection of filter plates

In order to optimize the assay outcome, the appropriate pore size of the filter plate was selected to optimize the filtration time, while keeping the number of bacteria passing through the filter low. Table 4.1 lists some commercially available filter plates, and the experimentally determined filtration times required to filtrate 100 - 600  $\mu\text{L}$  of cultures of *P. aeruginosa* at OD = 5.0. In this selection, a filter plate with a pore size of 1.2  $\mu\text{m}$  was included to compare the efficiency of filtration, although it was considered as too large because bacteria may pass through it.

Table 4.1 Comparison of filtration performance among a set of filter plates

Plate description	Pore size ( $\mu\text{m}$ )	Vacuum pressure (inHg)	Filtered volume ( $\mu\text{L}$ )	Cells per well (CFU)	Filtration time
Millipore GV, hydrophilic low protein binding Durapore®	0.22	5 - 10	100	$3.5 \times 10^8$	> 5 min
Millipore HTS hydrophobic high protein binding Immobilon P®	0.45	5 - 10	100	$3.5 \times 10^8$	> 5 min
AcroPrep™ Supor®	0.45	20-25	100	$3.5 \times 10^8$	1-3 min
AcroPrep™ Supor®	0.45	20-25	600	$1.3 \times 10^9$	> 5 min
AcroPrep™ Advance PTFE solvent resistant membrane	0.45	20-25	100	$3.5 \times 10^8$	N.A.
MultiScreen <sub>HTS</sub> -DV	0.45	20-25	100	$3.5 \times 10^8$	~ 15 s
MultiScreen <sub>HTS</sub> -DV	0.65	20-25	100	$3.5 \times 10^8$	~ 10 s
AcroPrep™ Supor®	1.2	20-25	100	$3.5 \times 10^8$	35 s
AcroPrep™ Supor®	1.2	20-25	200	$3.5 \times 10^8$	2 min

The plate with the smallest pore size of 0.22  $\mu\text{m}$  took the longest, more than 5 min, to filtrate 100  $\mu\text{L}$  of solution, while the plate with the largest pore size of 1.2  $\mu\text{m}$  took 35 s to filtrate the same volume. The best filtration times were achieved by filtrating 100  $\mu\text{L}$  with MultiScreen<sub>HTS</sub>-DV filter plates with pore sizes of 0.45 and 0.65  $\mu\text{m}$ .

To check whether the filters effectively retained bacteria, a plate containing 100  $\mu\text{L}$  of the bacterial solution at OD<sub>600</sub> = 5.0 without antibiotics was centrifuged for 30 min, and the filtrate was collected onto a receiver plate. The filtrated solutions were spot-plated onto an LB-agar plate. As shown in Figure 4.4, the number of *P. aeruginosa*'s CFUs after filtration through a 0.45- $\mu\text{m}$  filter plate reduced drastically as compared to a 0.65- $\mu\text{m}$  filter plate. The CFUs after filtration of *E. coli* and *S. aureus* were also reduced. Thus, the filter plate of choice of the HT screening was the MultiScreen<sub>HTS</sub> DV 0.45  $\mu\text{m}$  filter plate, as it allowed the fastest filtration and better cell retention, providing the assay with strain transferability for further screening studies.

Figure 4.4 Remaining colonies in the filtrate solution after centrifugation of 100  $\mu\text{L}$  of bacterial solutions at  $\text{OD}_{600} = 5.0$  onto a receiver plate through MultiScreenHTS DV filter plates with a pore size of 0.65  $\mu\text{m}$  and with 0.45  $\mu\text{m}$

Figure 4.5 Experimental setup for fast filtration and efficient washing of bacterial cells after incubation: a) filter plate, b) vacuum manifold, c) filtrate trap, d) vacuum pump, e) automatic pipetting robot, f) PC to control the automated pipetting workflow.

Figure 4.5 displays the experimental setup used for fast filtration assisted by a Bravo pipetting robot. The physical proximity of the vacuum manifold to the pipetting robot enables the user to stop the incubation and to add the lysis solvent in approx. two minutes, including the time for removing the supernatant and washing the cells twice. As a result, the dead times before extraction of the internalized compound reduced drastically from 30-50 min with deep-well plates, to 1-2 min with filter plates.

#### 4.1.2.2 Assurance of bacterial cells intactness

Another important aspect of the assay is to guarantee that the concentration used for uptake measurements does not compromise the intactness of the bacterial cells throughout the workflow – especially if potent, bactericidal antibiotics are tested. Determining bacterial viability gives an indication of their survival to antibiotic treatment after the exposure.

For this purpose, bacterial cells were incubated for one hour with a gradient of antibiotic concentrations under the same conditions as for uptake studies, serially diluted with fresh buffer and spot-platted on LB-agar plates to assay viability (Figure 4.6). Thus, the highest antibiotic concentration for uptake studies is the one that does not decrease the number of CFUs. In this example, *P. aeruginosa* at an OD = 5.0 tolerates a concentration up to 0.8 µg/mL of ciprofloxacin without compromising viability, while meropenem concentrations could go up to 100 µg/mL.

Figure 4.6 Colonies of *P. aeruginosa* after being treated for 1 h with a gradient concentration of ciprofloxacin (left) and meropenem (right). The first row was serially diluted downwards in a plate, and 2 µL of each well was spot-platted in an LB agar plate and incubated for 24 h at 37°C

#### 4.1.2.3 Time-course accumulation profiles

Monitoring the compound accumulation over exposure time poses a dynamic advantage over fixed-time analysis. Unlike single time-point analysis, time-course accumulation studies provide information on the first cell-compound interactions, the possible saturation points and the possible modifications of the compound once internalized.

This assay seems capable of showing the dynamic process of antibiotic accumulation (depicted in Figure 4.7). When exposed to an initial concentration of 100 ng/mL, *P. aeruginosa* accumulates ciprofloxacin increasingly during the first 10 min, reaching a plateau at 0.05 ng per well containing  $2.1 \times 10^8$  CFUs. When bacterial cells were incubated with CCCP for 5 min

before incubation with ciprofloxacin, the accumulated amounts of ciprofloxacin increased drastically by more than 5-fold (see Figure 4.7a). The depolarization of the membrane by CCCP has been previously employed as a control for enhanced uptake (Piddock and Johnson 2002). This increased accumulation is comparable to the profile of 200 ng/mL as initial concentration (Figure 4.7b). This curved profile is characteristic of ciprofloxacin and it was described extensively before (Piddock 1991; Piddock and Johnson 2002).

Figure 4.7 Time-course profiles for antibiotic uptake in *P. aeruginosa*. a) Ciprofloxacin uptake with and without pre-incubation with 100  $\mu$ M CCCP for 5 min. b) Ciprofloxacin uptake at different initial concentrations. c) Meropenem uptake at different concentrations. Error bars are the standard deviation of three replicates ( $n=3$ ) for ciprofloxacin and two replicates for meropenem ( $n=2$ )

Meropenem accumulation profiles show a different trend, as shown in Figure 4.7c. For all initial concentrations, there is an accumulation of compound during the first 5 min, and then it continuously decreases until a value close to zero. This behavior has not been reported earlier in accumulation studies. This profile could be characteristic of active efflux, induced by the rapid uptake of the compound, leading to a resistant phenotype. To prove that *P. aeruginosa* PA14 wild type was not resistant to meropenem, a susceptibility test was performed, showing that the strain has a MIC of 1  $\mu$ g/mL (Figure 4.8).

Figure 4.8 Susceptibility test of *P. aeruginosa* PA14 wild type to meropenem. Dots are the average value of duplicates and the standard deviation is represented by the error bars

#### 4.2 Uptake of antibiotics in Gram-negative bacteria: *E. coli* and *P. aeruginosa*

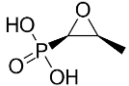

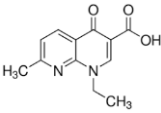

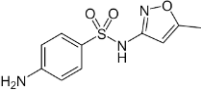

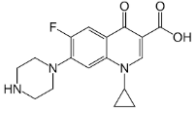

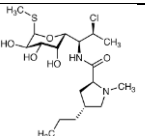

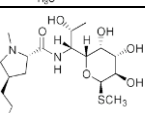

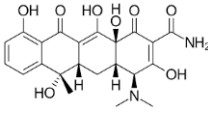

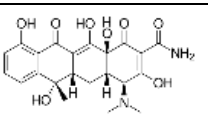

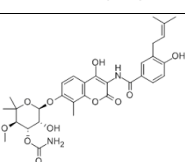

To prove the applicability of the described assay, the accumulation profiles for a panel of antibiotics were determined for *E. coli* and *P. aeruginosa* when treated at the same molar concentrations of 200  $\mu\text{M}$ . These compounds are listed and ordered by mass concentration in Table 4.2. The advantage of plotting the accumulation of a determined compound in both strains upon the same initial concentration is that their accumulation can be directly compared without the need for correcting for unspecific binding. However, despite having both the same  $\text{OD}_{600} = 5.0$  for antibiotic incubation, PA14 WT and *E. coli* MG1655 had different CFU count. Therefore, the values in  $\mu\text{mol}$  obtained were normalized to  $10^{12}$  CFU for a direct comparison between both strains and shown as time-course accumulation curves (Figure 4.9).

Overall, the quantities of compounds tend to increase over incubation time, and many of the accumulation profiles reach a plateau after 20 min (ciprofloxacin, tetracycline, tigecycline, and sulfamethoxazole). Nalidixic acid was the compound that accumulated the most in *P. aeruginosa*, reaching 120  $\mu\text{mol}$  per  $10^{12}$  CFU after 40 min, showing a higher accumulation than in *E. coli*. Another compound that presented better accumulation in *P. aeruginosa* is phosphomycin. It is important to note that these two compounds had the lowest molar masses compared to the others tested, and therefore, the lowest mass concentrations in the assay. Similarly, clindamycin showed a noticeable higher accumulation in *P. aeruginosa*.

The antibiotics that accumulated to the same extent in both strains were sulfamethoxazole and lincomycin. Ciprofloxacin accumulated less in *P. aeruginosa*, its uptake in *E. coli* after 10 min was 8.15  $\mu\text{mol}$  per  $10^{12}$  CFU, while in *P. aeruginosa* it was 1.38  $\mu\text{mol}$  per  $10^{12}$  CFU. In contrast to *E. coli*, *P. aeruginosa* did not accumulate tetracycline and tigecycline. Similarly, novobiocin showed higher accumulation in *E. coli*, reaching 2.33  $\mu\text{mol}$  per  $10^{12}$  CFU after 50 min, while *P. aeruginosa* showed 0.46  $\mu\text{mol}$  per  $10^{12}$  CFU over the total incubation period.

Although there is no direct relationship, compounds with higher molar mass tend to accumulate better in *E. coli*, and those with a lower molar mass accumulated better in *P. aeruginosa*. This is not a rule since ciprofloxacin should accumulate more in *P. aeruginosa* based on the same principle.

Table 4.2 Compounds used in uptake assays with *P. aeruginosa* and *E. coli*

Compound	Structure	Inhibited cellular function	Molecular weight (g/mol)	Molar concentration ( $\mu\text{M}$ )	Mass concentration ( $\mu\text{g/mL}$ )
Phosphomycin		Peptidoglycan synthesis	182.02	200	36.40
Nalidixic acid		DNA replication	232.24	200	46.45
Sulfamethoxazole		Folate pathway	253.28	200	50.66
Ciprofloxacin		DNA replication	331.35	200	66.27
Clindamycin		Peptide formation	424.98	200	85.00
Lincomycin		Peptide formation	461.01	200	92.20
Tetracycline		Translation of m-RNA	480.9	200	96.18
Tigecycline		Translation of m-RNA	585.65	200	117.13
Novobiocin		DNA replication	634.61	200	126.92

Figure 4.9 Time-course accumulation curves for a selected set of antibiotics incubated in 100 µL of bacterial solution at an OD<sub>600</sub> = 5.0 in NaPi buffer and at an initial concentration of 200 µM for all compounds. Error bars are the standard deviation of two biological replicates and two technical replicates (n=4)

### 4.3 Discussion

#### Antibiotic uptake in Gram-negative bacteria is species-specific

In spite of possessing an outer membrane with similar properties that hamper penetration, various Gram-negative organisms often present different susceptibility to antibiotics. Thus, it is not surprising that Gram-negative species present different rates of compound accumulation. Examples of this are tetracyclines, as they accumulated substantially in *E. coli* but not in *P. aeruginosa*, contrary to what was previously reported for radio-labeled tetracycline in *P. aeruginosa* (Li, Livermore, and Nikaido 1994).

Another example is nalidixic acid, which accumulated greatly in *E. coli*, and showed a remarkable accumulation in *P. aeruginosa*. These results are in agreement with Piddock et al. (1999), who reported that the accumulation kinetics of nalidixic acid in *P. aeruginosa* was notably faster than in *E. coli* (Piddock et al. 1999). With an artificial membrane approach, Graef et al. (2018) reported nalidixic acid to be the compound with the highest permeation rate among other gyrase inhibitors such as ciprofloxacin, norfloxacin and pipemidic acid (Graef et al. 2018), and the authors inferred that this effect was likely an effect of the molecular size. However, the results reported here paint a different picture (Figure 4.9), as phosphomycin, the smallest molecule of the set, and sulfamethoxazole was not among the highly accumulating compounds.

Recent studies postulated a set of accumulation rules in Gram-negative bacteria based on the inherent physicochemical properties of different compounds. Broadly, the proposed rules establish numeric thresholds related to the shape and rigidity of the molecules, as well as the degree of substitution of their amines (Richter et al. 2017; Richter and Hergenrother 2019). Although many compounds seem to be in agreement with the proposed rules, among them tetracycline and ciprofloxacin in *E. coli*, the present study shows that two Gram-negative species may show very different accumulation profiles of the same compound under identical incubation conditions.

Thus, in order to avoid an over-generalization of such accumulation rules in Gram-negative species, further data on antibiotic uptake in diverse species are still required. Comparing actual accumulation amounts across studies with different experimental setups is difficult, underlining the need for high throughput and easily strain-transferable uptake assay. The present medium-high throughput method allows for the systematic generation of data on antibiotic accumulation across species, which can be worthwhile for further in-depth structure-accumulation relationship studies.

### Detection of unlabeled and unmodified compounds

Several factors may lead to uptake misinterpretation in LC-MS/MS-based studies (Zgurskaya and Rybenkov 2020): first, the compound may be lost due to unspecific binding to the labware. In addition, the workup procedure that aims at removing residual compounds from the wells by washing may lead to a washout of compounds from the cells. Other factors may lead to a reduced signal, such as strong (noncovalent) interactions with e.g. proteins or cellular membranes due to imperfect protein denaturation or precipitation steps, making the compound unavailable for detection. Finally, compounds may undergo possible covalent modifications once they enter the cell (Rende-Fournier et al. 1993; Ramirez and Tolmasky 2010).

Monitoring the uptake of  $\beta$ -lactams via LC-MS/MS in bacterial cells is still challenging. After incubation with whole cells,  $\beta$ -lactams either a) are rapidly hydrolyzed by  $\beta$ -lactamases; or b) rapidly form long-lived covalent acyl-enzyme intermediates with their target PBPs. In both cases, the compounds are covalently modified and thus undetectable by the original, molecular ion-specific MRMs. Despite these challenges, meropenem was detected and quantified using the medium-high throughput assay, showing a rapid accumulation in the first minutes, and the amount dropped over time (Figure 4.7). This observation was possible due to the fast removal of the supernatant with an optimized filtration time (about 15 s). These results prove that it is incorrect to assume that  $\beta$ -lactams might serve as a negative control for LC-MS/MS-based accumulation studies (Richter and Hergenrother 2019).

For a complete picture of the uptake of  $\beta$ -lactams, a study that determines the accumulation of unmodified compound, its rate of hydrolysis and the formation of the corresponding covalent acyl-enzyme intermediate is still needed. In this regard, in 2017, Allam *et al.* monitored the accumulation of fluorophore-labeled ceftazidime conjugates in *E. coli*. After 30 min incubation and a subsequent wash, conjugated ceftazidime was found intracellularly. However, a such designed probe does not differentiate between the fluorescent signal coming from the hydrolyzed product and the one coming from the original compound. In the same study, a second ceftazidime conjugate was designed in such a way that it released its fluorophore after the cleavage of the  $\beta$ -lactam ring by the action of  $\beta$ -lactamases. This is an elegant approach to provide an overall insight into the uptake and transformation of  $\beta$ -lactams, by making use of two different conjugates for the same compound.

The herein proposed medium-high throughput assay could allow for direct detection of the hydrolyzed products of  $\beta$ -lactams by LC-MS/MS, although further development is required to obtain a purified hydrolyzed compound to develop MRMs and to perform standard curves. Similarly, other compounds that may undergo modification once intracellularly translocated are

suitable to be detected, such as aminoglycoside modification by N-acetylation, O-phosphorylation, or O-adenylation (Ramirez and Tolmasky 2010).

Moreover, since their lifetime is rather long, acyl-protein intermediates are good candidates for LC-MS/MS detection through PBP-targeted proteomics analyses. In targeted proteomics, the protein of interest undergoes proteolytic digestion, and the generated peptides are detected by selected reaction monitoring (SRM) (Chen and Liu 2019). In this way, an MRM could detect the formation of the surrogate peptide-acyl conjugate, as well as the free peptide from the same sample. However, in the current assay, the acyl-enzyme intermediates are likely precipitated together with other cell debris during the solvent-based lysis of bacteria. Thus, further optimization of this protocol might require lysing bacteria without compromising protein integrity, e.g. by sonication in an appropriate buffer with a multi-tip horn, in order to keep the assay throughput.

In summary, the present study provides a method to systematically evaluate the accumulation of different classes of antibiotics in bacteria. It was possible to detect and quantify label-free compounds accumulating in bacteria in small quantities, underlining the versatility and further applicability of LC-MS/MS-based methods. The development of a medium-high throughput method allowed the elucidation of time-course profiles of rapidly accumulated compounds and helped to differentiate the accumulation profiles between two Gram-negative species. Furthermore, the transferability of the assay to other species allows for reliable, robust and direct screening of accumulation of compounds, an increasingly important step in the development of novel antimicrobials to combat drug-resistant bacteria.

## 5. EFFECT OF ANTIBIOTICS IN *P. AERUGINOSA*

Antibiotics are known to have multiple effects on bacterial cells depending on the exposure concentrations (Davies, Spiegelman, and Yim 2006; Bernier and Surette 2013). At inhibitory concentrations, bacteria has been shown to exhibit metabolic responses that are associated with the compound's mode of action (Allen et al. 2004; Currie et al. 2016; Dörries, Schlueter, and Lalk 2014; Vincent et al. 2016; Yang et al. 2019; Zampieri et al. 2018; Zampieri et al. 2017). These studies have allowed the prediction of the mode of action of unknown compounds by comparing bacterial metabolic responses to those generated after exposure to reference antibiotics.

In the present work, a set of experiments was designed to elucidate the effects of exposure to sub-lethal concentrations of antibiotics on *P. aeruginosa*'s metabolic phenotype. Firstly, as a proof of concept, a medium high-throughput metabolomics workflow was carried out in order to assess whether sub-lethal concentrations of antibiotics with different modes of action exhibit distinctive metabolic fingerprints in *P. aeruginosa*. Secondly, the metabolic fingerprint of *P. aeruginosa* was evaluated under short and long exposure of clinically relevant antibiotics classes.

### 5.1 Metabolic phenotype under antibiotic perturbation

In order to investigate the phenotypic response of *P. aeruginosa* under antibiotic perturbation at non-lethal concentrations, three members of the fluoroquinolone class, three members of the macrolide class, and one  $\beta$ -lactam were selected (see Table 5.1). This allowed for the evaluation of inter- as well as intra-group variability. The treatment concentrations were selected as the highest at which the bacterial cells were still intact during the exposure time (see 4.1.2.2 Assurance of bacterial cells intactness).

As shown before, ciprofloxacin's concentration applicability went up to 0.8  $\mu\text{g}/\text{mL}$  and meropenem's concentration applicability reached 100  $\mu\text{g}/\text{mL}$  (see Figure 4.6), while for erythromycin, 1  $\text{mg}/\text{mL}$  did not decrease cell viability in 1 hour of treatment (see Figure 5.1). Thus, the exposure concentrations (hereon called non-killing concentrations) were selected by choosing an intermediate point from the gradient concentration used in these analyses, i.e., 0.2  $\text{mg}/\text{mL}$  for ciprofloxacin, 10  $\mu\text{g}/\text{mL}$  for meropenem and 50  $\mu\text{g}/\text{mL}$  for erythromycin.

Table 5.1 Experimental conditions to study the phenotypic response of PA14 WT to antibiotic perturbation in filter plates

Treatment	Antibiotic class	Concentration ( $\mu\text{g/mL}$ )	Initial OD <sub>600</sub>	Total incubation time (h)
Control (CON)	N.A.	0	1.0	2.0
Ciprofloxacin (CIPRO)	FQ	0.2	1.0	2.0
Levofloxacin (LEVO)	FQ	0.2	1.0	2.0
Lomefloxacin (LOME)	FQ	0.2	1.0	2.0
Azithromycin (AZI)	MA	50	1.0	2.0
Erythromycin (ERI)	MA	50	1.0	2.0
Clarithromycin (CLARI)	MA	50	1.0	2.0
Meropenem (MERO)	BLA	10	1.0	2.0

N.A. not applicable, FQ: fluoroquinolones, MA: macrolides, BLA:  $\beta$ -lactam.

Figure 5.1 Colonies of *P. aeruginosa* after being treated for 1 h with a gradient concentration of erythromycin. The first row was serially diluted downwards in a plate, and 2  $\mu\text{L}$  of each well was spot-plated in an LB agar plate and incubated for 24 h at 37°C

For consistency, the selected concentrations were applied to all the compounds within the same class. The experimental conditions were adjusted to a medium-high-throughput format in 96-deep well filter plates, since six replicates per condition were carried out simultaneously (see 3.4.2 Metabolomics in deep-well filter plates). Briefly, antibiotic solutions were added to a filter plate containing 1 mL of bacterial solution at OD<sub>600</sub> = 1.0 per well, and it was incubated at 37°C and 400 rpm for 2 hours. Samples were harvested simultaneously by fast filtration in a vacuum manifold. Filtered bacterial cells were washed and lysed and the extracted intracellular metabolome was analyzed in positive mode in a UPLC-ESI-QToF.

Untargeted metabolomics was performed by processing mzXML-formatted raw data with the XCMS R-based package for peak picking and feature detection, resulting in a table with 2376 features. After retention time cutoff of 0.3 min  $\leq$  RT  $\leq$  28 min (to discard the injection peak and the column wash), the number of features was reduced to 2110. As a quality control procedure, the coefficient of variation (CV) of the intensity of the internal standards (ISTDs) from all samples was calculated. For this data set, the intensity of all ISTDs was within an acceptable range of CV  $\leq$  20% (Table 5.2). In general, ISTDs account for variations in sample preparation,

elution time, and in the response of the detector (Wieling 2002). The use of a set of ISTDs for the intrametabolome extraction step (trimethoprim and glipizide, and nortriptyline) allows for correction in case of losses in sample preparation. On the other hand, the ISTDs for injection into the UPLC unit (caffeine and naproxen) help identifying variation in the device's functioning.

Table 5.2 Coefficient of variation (CV) of the internal standards for quality control of metabolomics in filter plates

Glipizide	Trimethoprim	Nortriptyline	Caffeine	Naproxen
5.99 %	4.13 %	15.37 %	4.45 %	4.63 %

The feature table was further analyzed to find the principal components (PC) that bring the most diversity among groups, without removing the intensity of the ISTDs and neither was a normalization carried out. The first two components with the highest explained variance are plotted in Figure 5.2a. Meropenem samples were the samples with better separation from the rest of the samples. At the same time, there is no perceptible separation among fluoroquinolone-treated samples from macrolide-treated samples nor untreated samples along PC2 (Figure 5.2a).

After a visual inspection on the pre-processed data, a series of highly intense peaks were found in all samples, including the blank samples (Figure 5.3). All samples were incubated and extracted with organic solvent identically. Since the metabolite extraction step carried out in the filter plates, the observed peaks likely are extractable compounds from the polymeric materials of plate. In total, 19 adjacent peaks with a difference in  $m/z$  value of 44.026  $m/z$  were detected between 6.5 and 11 min, showing a typical polyethylene glycol (PEG) mass distribution where the mass of the repeat unit ethylene oxide is 44 Da (Chen, Yu, and Li 2002) (for more details, see *Appendix II. Extractables from filter-plate-based metabolomics workflow***Error! Reference source not found.**).

The high intensity of such peaks could bring more similarity among the samples and the groups, which might hinder the separation among them in the principal component analysis (PCA). Therefore, a total of 84 features, including singly- and doubly-charged protonated ions and adducts, showed a  $CV \leq 15\%$  and were removed from the feature table. Similarly, the features corresponding to the five internal standards were removed from the feature table, as they appear in all the samples as well.

Figure 5.2 Principal component analysis for samples treated with four classes of antibiotics: fluoroquinolones (green), macrolides (blue), one  $\beta$ -lactam (black) and controls with no antibiotic addition (red). The preprocessed data were filtered by a retention time cutoff of  $0.3 \leq RT \leq 28$  min, and no normalization by the intensity of internal standards was carried out. a) Data before removing the PEG and ISTDs peaks, b) after removing the PEG and ISTDs peaks. Quantile normalization was carried out in order to better display the separation of the groups c) before and d) after removing the PEG and ISTDs peaks.

A second PCA was performed after removal of the common 89 features (Figure 5.2b), showing a light increase in the explained variance of PC2, from 15 to 17%, while the explained variance in PC1 remained unchanged. Generally, there was not a noticeable improvement on the separation among classes after the removal of the identified PEG and ISTDs features.

Figure 5.3 Total ion chromatograms (TIC) two metabolomics samples coming from the filter plate experimental set up showing a series of 19 peaks corresponding to PEG, likely coming from the plastic labware. Pooled sample in black and blank sample in grey. All the peaks appear in the blank samples, which were extracted with organic solvents identically to the rest of the samples.

In order to evaluate whether the treatments by antibiotic class could be better separated, quantile normalization was performed to the feature table, before and after removing the PEG as well as the ISTDs features. In a quantile normalization, the features of each sample keep their ordered position from the most intense to the least intense, but their intensity values are substituted by the mean value of the features in the same position across samples (Peterson and Cavanaugh 2019). Thus, samples belonging to groups with different distributions will have identical quantiles (therefore the name). Quantile normalization has been widely used in the analysis of large data sets coming from gene expression microarrays (Qiu, Wu, and Hu 2013), and it is applicable e.g. when only a minority of genes are expected to be differentially expressed (Hicks and Irizarry 2014).

The resulting feature table was further analyzed to find the principal components, and the first three components with the highest explained variance are plotted in Figure 5.2c-d. This time, a separation among antibiotic class was better detected along PC2. In general, replicates of the same treatment clustered together according to their antibiotic class. Only one replicate of each macrolide (AZI1, ERY1, and CLAR11) remained farther from the macrolide cluster and closer to the untreated controls and the  $\beta$ -lactam. The fluoroquinolone-treated samples were located mainly in the second quadrant of the scores plot for PC1 vs. PC2, while the untreated samples clustered within the third quadrant. Macrolide-treated samples were primarily located within the first and fourth quadrant, while  $\beta$ -lactam-treated samples were located in the lower-middle of the plot, mainly within the third quadrant (Figure 5.2c). It important to notice that, in

all cases, the distinction of individual antibiotic members within a class was not possible, as the variability within replicates was as large as between members of a class.

Although there was no sharp separation found among the groups, the distancing among classes showed in the PCA analysis is an indication of a class-specific phenotype of PA14 WT upon antibiotic perturbation. However, the experimental setup of this study showed an important drawback: the medium-high-throughput configuration prevented the measurement of OD<sub>600</sub> at the time of harvest, leading to the inability to measure any difference in growth due to the antibiotic activity. This aspect may have a strong influence on the available metabolite pool due to different biomasses at the harvest point. In order to account for any deviation in growth rate, a measure of biomass is needed; therefore, OD<sub>600</sub> was monitored in further experiments.

With the first insights of a class-specific phenotype for antibiotic treatment, additional questions were posed to interrogate whether the specific phenotype remains present at non-inhibitory concentrations instead of non-killing concentrations. For this purpose, both the immediate response to the treatment, as well as the long-term response were investigated.

Short- and long-term responses were investigated by exposing PA14 WT to antibiotics from three different classes at concentrations that did not show growth inhibition in a plate assay. The compounds selection for this analysis was in accordance with the antibiotic class most frequently used to treat *P. aeruginosa* (Pang et al. 2018). Aminoglycosides, such as tobramycin and gentamycin, and fluoroquinolones, such as ciprofloxacin and levofloxacin, are among the effective treatment against *P. aeruginosa*. Similarly, the treatment with macrolides such as azithromycin and erythromycin has been effective in patients with *P. aeruginosa* despite their high MIC values (Chalmers 2017).

## 5.2 Short and long exposure to non-inhibitory antibiotic concentrations

### 5.2.1 Determination of non-inhibitory concentrations

Unlike minimum inhibitory concentrations (MICs) assays, where bacterial cells are incubated at an initial  $OD_{600} = 0.05$ , non-inhibitory concentrations were determined by exposing a bacterial solution in the mid-log phase ( $OD_{600} = 0.5$ ) to different antibiotic concentrations overnight. The non-inhibitory concentrations per antibiotic class were selected so that no reduction in growth was observed in both members of the class (Figure 5.4).

Figure 5.4 Growth inhibition after 24 h at 37°C of incubation under antibiotic stress in BM2 medium starting with an initial  $OD_{600}=0.50$  in a cuvette with a path length  $l = 1$  cm. Red circles show the selected concentration for short- and long-term exposure experiments. The y-axis is the  $OD_{600}$  of 100 µL in a microplate. Error bars are the standard deviation of three replicates ( $n=3$ )

### 5.2.2 Design of experiment

The immediate responses of bacteria to antibiotic treatment was evaluated by the short exposure of bacterial cells to the non-inhibitory concentrations of the selected compounds. In contrast, the long-term responses to antibiotic treatment were evaluated by the long exposure to the same non-inhibitory concentration of compounds. In order to avoid undesired deviation in the metabolomics samples due to batch effects, both the short- and long-exposure treatment was carried out in one experiment.

Briefly, 3-mL cultures with an initial  $OD_{600} = 0.05$  were incubated in test tubes on an inclined rack to favor aeration. The long exposure was achieved by adding the antibiotic solutions at the beginning of the incubation and harvesting the bacterial cells at  $OD_{600} = 1.0$  (see Table 5.3). Short exposure samples were grown in the medium until  $OD_{600} = 0.5$  and incubated with antibiotic solutions until the  $OD_{600} = 1.0$  (see Table 5.4). As the number of samples to handle went to 48,  $OD_{600}$  monitoring was carried out by removing 100 µL of solution from each tube and transfer them to clear, flat bottom 96-well plates to be measured in a plate reader. Thus,

the equivalent of a final OD<sub>600</sub> = 1.0 measured in cuvettes with 1-cm path length is OD<sub>600</sub> = 0.4 measured in plates with 100  $\mu$ L of solution.

Table 5.3 Experimental conditions in the long exposure of PA14 WT to non-inhibitory concentration of selected antibiotics

Treatment	Concentration ( $\mu$ g/mL)	Antibiotic class	Initial OD <sub>600</sub> <sup>a</sup>	Final OD <sub>600</sub> <sup>b</sup> per replicate			Exposure time (h)

<sup>b</sup> measured in a plate reader with 100  $\mu$ L of solution

Samples of PA14 WT were harvested at different incubation times in order to reach comparable OD<sub>600</sub> values, while all samples of PA14 gyrAparC were harvested simultaneously. Harvested bacterial cells were washed and lysed and the extracted intracellular metabolome was analyzed in positive mode in a UPLC-ESI-QToF.

### 5.2.3 Data analysis

Untargeted metabolomics was performed by processing mzXML-formatted raw data with XCMS Online for peak picking and feature detection, resulting in a table with 2786 features. From them, 640 features (22.97%) were identified by XCMS Online as first, second, third, and fourth isotope peaks, with single, double, and triple charges (Table 5.5). These features were removed for further analysis, leaving 2146 monoisotopic ions.

Table 5.5 Number of features identified as ion isotopes in short and long exposure to non-inhibitory concentrations of antibiotics

Isotopic peak	Ion charge		
	1+	2+	3+
[M+1]	350	76	37
[M+2]	112	6	21
[M+3]	32	1	1
[M+4]	2	0	2

After retention time cutoff of  $0.3 \text{ min} \leq \text{RT} \leq 28 \text{ min}$  (to discard the injection peak and the column wash), the number of features was reduced to 1744. The quality control for ISTDs showed that one replicate of ciprofloxacin at short exposure (SE\_CIPRO1) presented highly deviated ISTDs intensities and it was removed from the analysis (see Figure 5.5). After this depuration, normalization based on the intensities of ISTDs was carried out within an acceptable range of CV before and after normalization (Table 5.6).

Figure 5.5 Intensities of the internal standards for short and long exposure to antibiotics a) before and b) after removal of sample SE\_CIPRO\_1

Table 5.6 Coefficient of variation (CV) of the internal standards for quality control of metabolomics in filter plates

	Glipizide	Trimethoprim	Nortriptyline	Caffeine	Naproxen
Before normalization	4.10 %	3.42 %	5.11 %	3.16 %	4.45 %
After ISTDs normalization	3.59 %	3.36 %	4.27 %	3.82 %	3.75 %
After OD <sub>600</sub> normalization	48.94 %	50.00 %	54.85 %	49.26 %	51.24 %

To account for differences in optical density across treatments, a normalization based on OD<sub>600</sub> values was carried out. As the long exposure treatment with ciprofloxacin presented the lowest OD<sub>600</sub> values, the intensity of all the features from these samples was substantially compensated after the OD<sub>600</sub> normalization, bringing the CV of ISTDs around 50%. Although this variation was no longer within the acceptance range, the normalized data set was subjected to PCA, expecting only the replicates of LE\_CIPRO to be overcompensated.

Before PCA analysis, the intensities of the five ISTDs, as well as their adducts identified manually by retention time (RT) and MS information, were discarded from the data set. Additionally, macrolides and their adducts were identified by RT, MS, and MS/MS information and removed from the analysis. Neither fluoroquinolones nor aminoglycosides were identified by their exact mass or spectral information. In addition, the data set was separated into two subsets, one for short-exposure treatment and one for long-exposure treatment, including the respective untreated controls.

As shown in Figure 5.6, fluoroquinolone-treated samples mostly remain separated from the rest of the treated and untreated samples for both short and long exposure. Moreover, macrolide-treated samples and aminoglycoside-treated samples were clustered together in both cases. In the short exposure, untreated control samples formed an independent cluster separated from the rest of the treatments Figure 5.6a. Ciprofloxacin-treated samples remained farther from the rest of the samples, and they did not cluster together with levofloxacin-treated samples.

In the long exposure, the samples of ciprofloxacin and levofloxacin treatment clustered together among replicates, but they did not form a fluoroquinolone-treatment cluster Figure 5.6b. In this analysis, replicates from LE\_CIPRO were expected to distant from the rest of the samples as the OD<sub>600</sub> normalization compensated greatly the intensity of all their features. Surprisingly, also LE\_LEVO formed a distant cluster away from the rest of the samples. Besides, there was no separation of the untreated controls from the macrolide-treated samples.

Figure 5.6 Principal component analysis for samples treated with sub-inhibitory concentrations of antibiotics upon a) short exposure (SE) and b) long exposure (LE). Color code for treatment: untreated controls (red), fluoroquinolones (green), macrolides (blue), aminoglycosides (black).

In order to compare short- and long-exposure treatments, a correlation matrix was performed including all samples from all the groups (Figure 5.7). Four main clusters were identified: I) all ciprofloxacin-treated samples and LE\_LEVO samples, II) all levofloxacin-treated samples and SE\_CIPRO, III) all short-exposure samples (except for SE\_CIPRO), and IV) all long-exposure samples (except LE\_LEVO) and untreated controls.

Together with Figure 5.6, the correlation matrix in Figure 5.7 shows that the response of PA14 WT to fluoroquinolone treatment is distinctive from the other treatments and the untreated controls, as cluster I and II form a larger fluoroquinolone cluster. Additionally, long exposure to macrolides and aminoglycosides did not exhibit a distinct response, in comparison with the untreated controls. It is important to note that PA14 WT responded more readily to a short exposure to all antibiotic classes, and even more, to fluoroquinolone treatment.

Figure 5.7 Correlation matrix of short- and long-exposure treated samples to non-inhibitory concentrations of antibiotics. Four clusters are highlighted: I) and II) fluoroquinolone treatment, III) short-exposure treatment (excluding ciprofloxacin), and IV) long-exposure treatment and untreated controls. SE: short exposure, LE: long exposure.

Additionally, a heatmap with hierarchical clustering was performed to detect similarities and differences in short- and long-exposure treatments (Figure 5.8). For this,  $\log_2$ -transformed fold changes ( $\log_2$ -FC) were calculated by subtracting the  $\log_2$ -mean values of the untreated controls from the  $\log_2$ -mean values of each treatment group; thus, over-produced features had a positive  $\log_2$ -FC, while under-produced metabolites had a negative  $\log_2$ -FC.

Indistinctly of the exposure time, fluoroquinolone-treated samples formed a group separated from the rest of the treatments, as shown in the column-wise hierarchical cluster in Figure 5.8. LE\_CIPRO presented the most marked changes in feature abundance with respect to the controls, which could not be associated with a distinctive biological phenotype, but rather to artifacts due to the  $OD_{600}$  normalization step. On the one hand, the intensity of all the features in LE\_CIPRO replicates was substantially compensated because of their low  $OD_{600}$  values. On the other hand, low  $OD_{600}$  values in these replicates resulted in many features with lower intensity than the detection threshold of 400 total counts, showing a strong negative  $\log_2$ FC (after correction for missing values).

Figure 5.8 Heat map of feature fold-changes for samples treated with non-inhibitory concentrations of antibiotics upon short exposure (SE) and long exposure (LE). Four regions of interest are highlighted: 1), 2) and 3) over-produced features in samples treated with fluoroquinolones, 4) over-produced features in samples upon short-exposure treatment, and 5) over-produced features in samples treated with aminoglycosides and macrolides. Log<sub>2</sub>-transformed fold change (Log<sub>2</sub>FC) was calculated from the mean values of triplicates, by subtracting the log<sub>2</sub> values of each condition from the untreated control samples. Scaled Log<sub>2</sub>FC was performed as a default function in R Studio for visualization of over-produced metabolites (in red) and under-produced metabolites (in blue) with respect to the untreated controls.

The row-wise hierarchical clustering allowed for the detection of four regions of interest, which were detected visually and highlighted on the heat map (Figure 5.8). The highlighted regions 1, 2, and 3 correspond to two subsets of features that were found to be uniquely over-produced under fluoroquinolone treatment. The highlighted region 4 corresponds to a subset of features that were found to be over-produced particularly under short exposure to antibiotics. Finally, the highlighted region 5 corresponds to a subset of features over-produced under macrolide and aminoglycoside treatment (see *Appendix III. Feature table - comparison between short and long exposure*).

To identify the nature of these features, a general feature identification procedure was applied to the whole data set first. MS/MS identification of a pooled sample (a sample containing the same volume of each replicate from all groups) was carried out in Bruker Compass DataAnalysis 4.2 by finding the molecular features and performing a comparison with an *in-house* library. The search was refined manually to detect unidentified adducts and *in-source* fragments of the matching features, labeled with a preceding asterisk (putative annotation). In total, 85 features were structurally assigned to 54 metabolites (for more details, see *Appendix III. Feature table - comparison between short and long exposure*).

The features belonging to regions 1, 2, 3, 4, and 5 of the heat map were filtered out visually. Region 1, 2 and 3 together accounted for 171 features, from which only 11 belonging to region 2 were annotated (see Table 5.7). Region 4 consisted of 117 features, from which only 11 were annotated (see Table 5.8). Region 5 consisted of 113 features, from which none were identified (see *Appendix III. Feature table - comparison between short and long exposure*).

Fluoroquinolone treatment enhanced the production of the identified lyso-phosphatidyl ethanolamines significantly in both exposures (Table 5.7). Additionally, two identified 2-alkyl-hydroxyquinoline-N-oxides (-QNO) were also over-produced, although not as significant. It is important to note that these identified features were found in region 2 of the heat map, where the fluoroquinolone treatment showed over-production. In contrast, treatment with macrolides and aminoglycosides showed under-production (Figure 5.8). On the contrary, rhamnolipids found in region 4 of the heat map were significantly over-produced under short exposure of all treatments, except for ciprofloxacin (Table 5.8).

Other important identified features did not cluster in any of the mentioned regions of interest, such as secondary metabolites associated with virulence factors: a) quorum sensing molecules HHQ and PQS, and b) phenazines and pyocyanin (Figure 5.9). PQS did not show any significant change in abundance under any treatment. However, HHQ presented a significant reduction in abundance under short and long exposure to ciprofloxacin, as well as under short exposure to levofloxacin, but not under long exposure to it. Additionally, HHQ was significantly less abundant under short exposure to aminoglycosides.

Without exception, the abundance of the identified phenazines (pyocyanin, phenazine-1-carboxylic acid, phenazine-1-carboxamide, and 1-hydroxyphenazine) did not change significantly under any treatment, except for the long exposure to ciprofloxacin (Figure 5.9). However, since these features showed missing values in LE\_CIPRO replicates, the significant changes are most likely an artifact of reduced OD<sub>600</sub> values.

Figure 5.9 Box plots of identified virulence factors in samples of PA14 WT treated under short (SE) and long exposure (LE) to non-inhibitory concentrations of antibiotics: fluoroquinolones (green), macrolides (blue) and aminoglycosides (black). The first box plot correspond to the untreated control (red). \*\*\* for  $p$ -value  $\leq 0.001$ , \*\* for  $0.001 < p$ -value  $\leq 0.01$ , \* for  $0.01 < p$ -value  $\leq 0.05$ , with respect to the untreated control

In summary, PA14 WT treated with non-inhibitory concentrations of antibiotics presented distinctive phenotypes upon short- and long-exposure treatment. Remarkably, responses to fluoroquinolone-treatment were differentiated from the treatment with macrolides and aminoglycosides. The responses to the treatment with these last two classes of antibiotics were impossible to differentiate under the conditions applied (non-inhibitory concentrations under short and long exposure).

Although important for a matter of comparison between the two experiments, the selected concentrations might have had different inhibitory effects upon short and long exposure. Proved by different harvest points under low exposure, the bacterial growth was impaired at the selected concentrations meaning that the assumption of non-inhibitory concentrations is no longer valid at those conditions.

Most importantly, the strong response to fluoroquinolones at sub-lethal concentrations poses the question of whether this response originates from the inhibitory effect of target-compound specific interactions or due to off-target effects. To solve this question, an experiment to study the direct effects caused by gyrase/topoisomerase inhibition was designed (see 6. Direct and indirect responses upon antibiotic exposure).

### **5.3 Discussion**

#### **Antibiotics cause specific responses according to their mode of action**

In this study, a metabolomics approach to evaluate the metabolic response of PA14 WT upon treatment with different classes of antibiotics was undertaken. Differentiated metabolic profiles were observed when using compounds within classes with very distinctive molecular targets: fluoroquinolones (targeting the topoisomerases type II and IV in *P. aeruginosa*), macrolides (with high affinity to the bacterial ribosome) and  $\beta$ -lactams (with high affinity to PBPs).

Nevertheless, no clear distinction was found between antibiotics that inhibit protein synthesis as a mechanism of action, such as macrolides and aminoglycosides, even when the exposure concentrations varied greatly from class to class (20x higher for macrolides). This observation was consistent with previous reports on the study of the mode of action of antimicrobials (Zampieri et al. 2018; Zampieri et al. 2017).

As protein synthesis inhibitors, macrolides block peptidyl-tRNAs chain elongation by binding to the peptidyl transferase center (PTC) located in the large subunit (LSU) of the bacterial ribosome. Aminoglycosides, however, increase the error rates during the elongation chain of peptidyl-tRNAs by binding to the 16S rRNA as their primary target in the small subunit (SSU), but they also bind to the 23S rRNA as their secondary target in the LSU (Romanowska, Reuter, and Trylska 2013; O'Sullivan et al. 2018). These differences seem to have similar alterations in the metabolic profile, regardless of the ribosomal subunit affected. Bacterial metabolic responses associated to protein synthesis inhibitor have been reported before, using concentrations close to the IC50 and the MIC (Zampieri et al. 2018; Zampieri et al. 2017), where the affected pathways were principally the biosynthesis and metabolism of amino acids, and the biosynthesis of aminoacyl-tRNAs (Dörries, Schlueter, and Lalk 2014; Zampieri et al. 2017). However, under the experimental conditions in the present study, no significant changes in the abundance of the identified amino acids were found, presumably due to the absence of growth inhibition.

#### **Non-inhibitory concentrations of antibiotics cause immediate metabolic changes**

PA14 WT responded readily to sudden exposure to antibiotics, where the perturbing agent was introduced while cells were exponentially growing. Signature profiles were identified for groups treated upon short exposure to non-inhibitory concentrations, in comparison with groups treated under long exposure to the same concentrations. Rapid changes induced by

short exposure to aminoglycosides and macrolides were rather heterogeneous, while the treatment with fluoroquinolones exhibits a different profile.

Rhamnolipids were found to be significantly increased under short exposure to non-inhibitory concentrations of aminoglycosides, and macrolides, and less significantly to fluoroquinolones. Rhamnolipids have a complex regulation circuitry in *P. aeruginosa*, and they are widely considered as virulence factors, as well as important contributors to the formation and maturation of biofilm (Chrzanowski, Ławniczak, and Czaczyk 2012). In agreement with previous reports, aminoglycosides contribute to the biofilm generation at sub-inhibitory concentrations (Hoffman et al. 2005; Linares et al. 2006). Conversely, *P. aeruginosa* treated with azithromycin has shown delays in biofilm formation (Nalca et al. 2006) and reduced production of rhamnolipids (Tateda et al. 2001). A possible explanation for the diversity of the result may rely on the difference of experimental setups used in the studies.

Since rhamnolipids biosynthetic pathway shares steps in common with lipid metabolism, alginate production, and AQS biosynthesis, their difference in abundance might be the result of a set of adaptations towards antibiotic stress.

#### **Fluoroquinolones cause a strong metabolic response even at sub-inhibitory concentrations**

Both ciprofloxacin and levofloxacin presented a better antimicrobial efficacy in terms of inhibitory concentrations than the rest of the compounds. This was observable also at the non-inhibitory level, as the applied concentrations for fluoroquinolones were 80x lower than for macrolides and 4x lower than for aminoglycosides. Immediate and long-term responses of *P. aeruginosa* treated with fluoroquinolones were stronger and more distinctive than those under other antibiotic class treatment, even by trying to ensure the comparison of harvested cultures at the same cell density.

Treatment with fluoroquinolones showed some unidentified features that responded more readily than in any other of the treatments. Additional work on the identification of some of these features is needed. There were also identified features that responded more strongly to fluoroquinolone treatment, mainly LPEs and some 2-alkyl-4hydroxyquinoline N-oxides (QNO) analogs. These metabolites showed significantly increased intensity in samples treated under short and long exposure of both ciprofloxacin and levofloxacin. LPE is evidence of alterations in lipid metabolism, while AQNOs themselves have been found to present antimicrobial properties (Heeb et al. 2011). Previous reports found that sub-MIC concentrations of fluoroquinolones in *P. aeruginosa*, specifically ciprofloxacin, induce biofilm formation and

reduce swimming and swarming (Linares et al. 2006), decrease siderophore production (Trancassini et al. 1992), enhance the mutation frequency (Wolter et al. 2007; Tanimoto et al. 2008), and induce the general SOS bacterial response (Brazas and Hancock 2005; Breidenstein, Bains, and Hancock 2012).

Although the disturbance in lipid metabolism due to fluoroquinolones is not yet understood, some studies highlight the interactions of fluoroquinolones across lipid layers (Cramariuc et al. 2012; Bensikaddour et al. 2008) and it has been shown that alteration in the LPS structure lead to a reduced compound translocation (Mingeot-Leclercq and Décout 2016), e.g. reduced fluoroquinolones accumulation (Everett et al. 1996). The present study shows that fluoroquinolones have an effect on *P. aeruginosa*'s lipid metabolism, even when treated at sub-lethal concentrations.

#### **Antibiotic concentrations for metabolomics studies are not standardized**

Treatment concentrations vary greatly in studies that aim to profile the response of microorganisms to antimicrobials. Some authors select sub-MIC concentrations based on the plate-assay determined measured MIC value, e.g. 0.1xMIC, 0.5xMIC or 0.8xMIC. Others make their selection based on the concentrations that do not affect bacterial growth. This shows that the selection of sub-inhibitory, sub-MIC, non-inhibitory, sub-lethal or non-killing concentrations is not yet standardized. Even the term “sub-inhibitory” often is confused with “sub-MIC”.

Yet, treatment concentrations can cause a strong inhibitory effect even when they are lower than the MIC values. For instance, Zampieri et al. analyzed the response of *E. coli* to a set of 10 antibiotics with a nontargeted metabolomics approach (Zampieri et al. 2017). For their study, they chose concentrations “close to” the concentration that inhibits 50% of the growth (IC50), and one concentration “close to” the MIC value. When compared to both “low” and “high” dosages, they found little deviations in the metabolic response, indicating that IC50 concentrations influence metabolic changes to an extent comparable to bacterial cell death.

Logically, non-inhibitory concentrations do not affect bacterial growth when compared with the untreated control. However, the growth conditions vary also from study to study, being unable to compare the effects of punctual concentrations across experiments with e.g. different carbon sources or different nutrient availability. Therefore, a complete study of antibiotic effects upon a range of concentrations, both sub-inhibitory and inhibitory, is still needed.

## 6. DIRECT AND INDIRECT RESPONSES UPON ANTIBIOTIC EXPOSURE

According to their concentrations, antibiotics may act as toxins at high concentrations, stress inducers at sub-lethal concentrations, or as cues or coercions at low, sub-inhibitory concentrations (Bernier and Surette 2013). One major challenge is to differentiate whether the effects induced by antibiotics at low concentrations are due to on-target effects as an adaptive response of the organism to partial inhibition of the target, or whether secondary, unknown targets induce additional responses. Under this scenario, the following hypothesis was posed: a target mutation that prevents compound binding should completely evade all effects caused by the primary target. Therefore, all responses of the organism should be triggered by interactions with other, secondary components (see Figure 6.1).

Figure 6.1 Experimental design to study the direct and indirect consequences of antibiotic exposure

## 6.1 Characterization of fluoroquinolone resistant strains

Two fluoroquinolone-resistant mutants were evaluated to select the most resistant to ciprofloxacin. The mutants were constructed with the introduction of one or two single nucleotide polymorphisms (SPN) in *gyrA* Thr83Ile and *parC* Ser87Leu to the ciprofloxacin-susceptible reference strain PA14 WT (Bruchmann et al. 2013), and were kindly donated by Prof. Dr. Susanne Häußler. The extent of resistance was evaluated by growth inhibition assays, and the sub-inhibitory concentrations were determined for PA14 WT, PA14 *gyrA* Thr83Ile (hereon PA14 *gyrA*) and PA14 *gyrA* Thr83Ile *parC* Ser87Leu (hereon PA14 *gyrAparC*). The values for their inhibitory concentrations are listed in Table 6.1. The calculation of sub- and inhibitory concentrations NIC, IC10, IC50, and MIC was based on the method previously reported by Lambert *et al.* 2000, where NIC is defined as the concentration above which growth inhibition starts (Lambert and Pearson 2000).

Table 6.1 Inhibitory concentrations of ciprofloxacin in susceptible and resistant *P. aeruginosa* strains in µg/mL

Strain	NIC	IC10	IC50	MIC
PA14 WT (WT)	0.016 ± 0.003	0.023 ± 0.000	0.059 ± 0.001	0.151 ± 0.005
PA14 <i>gyrA</i> T83I ( <i>gyrA</i> )	0.053 ± 0.026	0.127 ± 0.052	1.073 ± 0.068	12.983 ± 0.827
PA14 <i>gyrA</i> T83I <i>parC</i> S87L ( <i>gyrAparC</i> )	8.501 ± 0.598	10.440 ± 0.691	17.597 ± 0.985	29.833 ± 1.360

These results are consistent with previous data showing that GyrA is not the only target affected by ciprofloxacin in *P. aeruginosa* (Bruchmann et al. 2013). Inhibition of the DNA topoisomerase IV complex also accounts for the activity of this compound. By inserting a point mutation in *gyrA*, PA14 WT increased its tolerance to ciprofloxacin by 6.4 log<sub>2</sub>-units in MIC. Inserting a second mutation, but now in *parC* to the PA14 *gyrA* mutant, increased its resistance by only 1.2 log<sub>2</sub>-units in its MIC value. However, the rest of the sub-MIC concentrations (NIC, IC10 and IC50) changed substantially upon this second point mutation, as seen in Figure 6.2a.

Figure 6.2 Log2 fold-changes respect to the WT at MIC and sub-MIC concentrations, a) fold-change given by a point mutation in *gyrA* compared to the WT (dark blue), fold change given by point mutations in *gyrA* and *parC* compared to the *gyrA* mutant (light blue), b) global fold-change given by both mutations in *gyrA* and *parC* compared to the WT (green).

When compared with the WT, PA14 *gyrAparC* increased the tolerance to the whole range of inhibitory concentrations more homogeneously (Figure 6.2b). This analysis shows how the contribution of each individual mutation to the overall resistance is distributed over a range of concentrations. While the point mutation in *gyrA* provides resistance to highly inhibitory concentrations, the additional mutation in *parC* extends the tolerance toward the low range of inhibitory concentrations. To account for a minimal drug-target interaction, the PA14 *gyrAparC* mutant was selected for studying the metabolic response upon ciprofloxacin treatment. This because its range of inhibition does not overlap with the reference WT strain as shown in Figure 6.3, and the exposure to WT sub-inhibitory concentrations (sub-MIC<sub>WT</sub>) does not affect the growth of *gyrAparC*.

Figure 6.3 Growth inhibition of resistant and reference strains under ciprofloxacin stress after 24 h at 37°C of incubation in BM2 medium. The y-axis is the OD<sub>600</sub> of 200 µL in a microplate. Error bars are the standard deviation of two independent experiments with two replicates (n=4)

## 6.2 Selection of antibiotic concentrations for metabolome experiments

In order to select the appropriate concentrations for metabolomics experiments, the growth inhibition of ciprofloxacin in both strains, PA14 WT and PA14 *gyrAparC*, was monitored over 12 hours. Briefly, 3-mL cultures, inoculated with the respective strain to an  $OD_{600} = 0.05$ , were incubated at 37° and 150 rpm under the inhibitory concentrations for WT listed in Table 6.1. Exposure to inhibitory concentrations affected growth in PA14 WT, while PA14 *gyrAparC* treated with WT inhibitory concentrations showed no effect in growth, even at  $MIC_{WT}$  (Figure 6.4). Although ciprofloxacin at  $MIC_{WT}$  inhibited the growth of PA14 WT over the first 12 h, the cultures reached visibly high turbidity after been left incubating overnight at 37°C (not shown); contrary to what was expected, since the treatment of PA14 WT with MIC should inhibit the growth after 24 h.

Figure 6.4 Growth curves for PA14 WT and PA14 *gyrAparC* under ciprofloxacin treatment at MIC and sub-MIC concentrations. Cultures were incubated at 37° and 150 rpm in 10-mL test tubes inclined at 60°. Aliquots of 100 µL were taken at a fixed time from all the replicates of both strains and transferred to the wells of a microtiter plate to measure the  $OD_{600}$ . Error bars are the standard deviation of three replicates ( $n=3$ )

As a comparison, PA14 WT growth assays in microtiter-plate format and in test-tube format were carried out. As shown in Figure 6.5, the curve from the test-tubes format resulted in being shifted to the right, increasing the concentration required for different degrees of inhibition when compared to the plate format. Furthermore, the calculation of sub- and inhibitory concentrations was carried out and listed in Table 6.2. The MIC in tubes was about 9-fold

higher than MIC in plates, while IC50 in tubes was over 4-fold higher than in plates. NIC and IC10 in tubes were about 1.5- and 2-fold higher than in plates, respectively.

Figure 6.5 Comparison of PA14 growth inhibition assay in a plate (96-well microtiter plates containing 200 µL of culture) and in tubes (test tubes containing 3.1 mL of culture) under ciprofloxacin stress after 24 h at 37°C of incubation in BM2 medium. The antibiotic solutions were freshly prepared, and all the dilutions were performed from the same stock. The y-axis shows the percentage of growth for each format calculated based on the OD<sub>600</sub> measured for the untreated controls (not shown). Error bars are the standard deviation of 3 replicates (n=3)

Table 6.2 Sub- and inhibitory concentrations for PA14 WT in a plate and tubes in µg/mL

Format	Culture volume (mL)	NIC	IC10	IC50	MIC
Plate	0.2	0.016	0.023	0.059	0.151
Tubes	3.1	0.025	0.048	0.255	1.364

For metabolomics experiments, PA14 WT and PA14 gyrAparC were cultivated in tubes and exposed to the whole range of sub- and inhibitory concentrations determined in plates for WT, including the value for MIC<sub>WT</sub>. Briefly, 3-mL cultures were incubated at 37°C and 150 rpm under the inhibitory concentrations for WT and harvested when the OD<sub>600</sub> value was close to 1.0 (Table 6.3). Samples of PA14 WT were harvested at different incubation times in order to reach comparable OD<sub>600</sub> values, while all samples of PA14 gyrAparC were harvested simultaneously. PA14 WT samples treated with MIC<sub>WT</sub> reached an OD<sub>600</sub> close to 1.0 after 28 h of incubation.

Table 6.3 Harvest information of samples un- and treated with ciprofloxacin concentration for metabolomics experiments

Treatment	Initial concentration ( $\mu\text{g/mL}$ )	Incubation time (h)	Final OD <sub>600</sub> per replicate		
			1	2	3
WT_CON	0	6.5	1.28	1.08	1.24
WT_NIC	0.016	7.0	0.97	1.07	0.94
WT_IC10	0.023	7.0	1.01	1.01	0.97
WT_IC50	0.059	9.0	0.99	1.07	0.94
WT_MIC	0.151	28.0	1.39	1.44	1.24
gyrAparC_CON	0	7.0	1.23	1.14	1.34
gyrAparC_NIC	0.016	7.0	1.06	1.03	1.12
gyrAparC_IC10	0.023	7.0	1.19	1.2	1.17
gyrAparC_IC50	0.059	7.0	1.18	1.19	1.14
gyrAparC_MIC	0.151	7.0	1.00	1.00	1.13

### 6.3 Data analysis and feature identification

An untargeted analysis was applied for the samples of PA14 WT and PA14 gyrAparC treated with ciprofloxacin. Briefly, harvested bacterial cells were washed and lysed; the extracted intracellular metabolome was analyzed in positive mode in a UPLC-ESI-QToF.

#### 6.3.1 Data filtering

Raw metabolomics data were pre-processed in XCMS Online for peak picking and feature detection. The complete pre-processed metabolomics data consisted of a total of 7344 features. Out of them, 1334 features (18.16%) were identified by XCMS as first, second, third, and fourth isotope peaks, with single, double and triple charges (Table 6.4). These features were removed for further analysis, leaving 6010 monoisotopic ions.

Additionally, a retention time cutoff of  $0.3 \text{ min} \leq \text{RT} \leq 28 \text{ min}$  was applied, so 770 features were filtered out. Five compounds were used as internal standards: glipizide, trimethoprim, and nortriptyline as extraction standards, and caffeine and naproxen as injection standards. The data were normalized by the intensity of the internal standards (ISTDs) and OD<sub>600</sub>, and the intensity of these ISTDs and their adducts were filtered out, resulting in a feature table with 5216 candidates to be identified as metabolites, as shown later in Figure 6.8.

Table 6.4 Number of features identified as ion isotopes in metabolomics data

Isotopic peak	Ion charge		
	1+	2+	3+
[M+1]	768	173	29
[M+2]	215	25	18
[M+3]	81	6	2
[M+4]	13	4	0

### 6.3.2 Feature identification in positive mode

With the use of two MS/MS *in-house* and two commercial compound libraries (*in-silico* generated MS/MS spectra from MetaboBase Personal Library and LipidBlast), 193 features were successfully annotated, corresponding to 87 unique metabolites. One of the libraries is *P. aeruginosa*-specific and contains spectral information from representative secondary metabolites. Direct MS/MS library matching accounted for an identification yield of 3.70%, including in-source fragments, adducts, and multiple-charged ions. As it is shown later in Table 6.5, this yield of identification was improved by another two means of spectral clustering, as well as putative annotation by manual scrutiny.

Followed by the library matching identification, mzXML-formatted data for PA14 WT treated and untreated samples with triplicates was submitted to analysis via on-line GNPS (Global Natural Product Social Molecular Networking) library-based molecular networking, which performs a spectral alignment among samples and creates clusters of features with spectral similarity (Wang et al. 2016). GNPS molecular networking resulted in 938 features grouped in 51 clusters, from which nine were the most prominent and those with MS/MS matching with the GNPS library (Figure 6.6). The most representative classes of secondary metabolites in *P. aeruginosa*, alkyl-quinolones, phenazines, and rhamnolipids were grouped in three respective clusters. The cluster corresponding to alkyl-quinolones congeners consisted of 96 features, including HQ-, PQS- and QNO- related compounds, while the rhamnolipids cluster contained 57 features. The phenazine cluster contained only four features. A crowded cluster containing phenylalanine-related compounds but also pyocyanin was found with 40 features. A cluster containing phospholipids was generated with 20 features. Similarly, 12 glutamate-related features were clustered together, and seven features related to spermidine formed a separated cluster. A cluster containing glutathione was found with four features. Clusters for three of the internal standards were found as well: a cluster of nortriptyline with eight features, a cluster of glipizide with two features, and a cluster of trimethoprim with two features (for the complete cluster table, see *Appendix V. GNPS clustering*).

## Direct and indirect responses upon antibiotic exposure

Figure 6.6 Molecular networking of the identified features found by the GNPS algorithm. Every node corresponds to a feature with a defined  $m/z$  value (shown) and an RT (not shown). The width of the edges (in grey) corresponds to the cosine score as a measure of spectral similarity, the thicker the edge, the more spectral similarity among the features

Furthermore, a pooled sample of gyrAparC untreated samples (controls) was analyzed with CluMSID (Depke, Franke, and Brönstrup 2017, 2019), an R-based package that performs clustering of features with spectral similarity. Figure 6.7 depicts the resulting circular hierarchical clustering of 1172 features, grouped in 120 clusters, where the most populated clusters are highlighted. These data were analyzed manually to identify three of the most prominent clusters. Cluster #35 with 240 features corresponds to alkyl-quinolones congeners, cluster #8 with 186 features corresponds to rhamnolipids, and cluster #1 with 106 features contains glutamate-related compounds. For cluster #2 with 94 features and cluster #3 with 140, there were no identified features (for the complete cluster table, see *Appendix VI. CluMSID clustering*).

Figure 6.7 CluMSID circular hierarchical clustering of 1172 features in a pooled sample of gyrAparC untreated control. Cluster #1: glutamate-related compounds, Cluster #8: rhamnolipids, Cluster #35: alkyl-quinolones, Cluster #2 and #3: not identified features

So far, three metabolite identification tools were applied: direct matching with MS/MS *in-house* and commercial libraries, feature clustering by GNPS-generated molecular network, and feature clustering by CluMSID. The last two resulted in two different tables with independent features that do not necessarily match with the original data set (feature table from XCMS Online). By comparing the exact mass and retention time of the features in the original data set with those in the cluster table (see 3.5.5 Feature identification), 763 features were matched with the GNPS cluster numeration, and 442 features were matched with the CluMSID cluster numeration. However, not all the cluster numbers could be identified, only 336 features with GNPS numeration and 293 features with CluMSID numeration were assigned an identification label (see Figure 6.8).

Identification labels were assigned according to the compound class: “AA” for aminoacids, “AQ” for alkyl-quinolones, “FA” for fatty acids, “Glu” for glutamic containing features, “Glutathion” for the glutathione-related features, “HSL” for homoserine-lactones, “Lip” for unidentified lipids, “Nuc” for nucleotides, “Phen” for phenazines, “Phenyl” for phenylalanine-related features, “PhosLip” for phospholipids, “Rha” for rhamnolipids, and “UDP” for features containing uridine diphosphate (see *Appendix VII. Annotation table - sub-MIC ciprofloxacin concentrations*). When a cluster contained one or more identified features, a label of the compound class was assigned; when a cluster contained only unidentified features, the complete cluster remained unlabeled. In total, 539 features were assigned with a class label.

Additional manual identification was carried out based on the RT, the exact mass of the molecular ion for each feature, and with the help of the assigned class labels, resulting in another 152 features with a putative label preceded by an asterisk (\*). The spectral information of features with putative labels was examined in Data Analysis to corroborate their exact mass and isotope distribution (for more details, see *Appendix IV. MS and MS/MS identification*).

Table 6.5 summarizes the feature identification strategy and the tools used. After feature filtering and identification, only 70.96% (5211 of 7344) of the features were considered candidates for being metabolites (Figure 6.8). With 564 features assigned with an annotation by means of any of the identification tools (539 with a class label and 25 without), the yield of identification raised to 10.82%, in comparison with a search strategy that is limited to direct matching with spectral libraries with 3.70%.

Figure 6.8 Feature filtering and identification after preprocessing with XCMS Online. 1334 features were filtered by monoisotopic signals with CAMERA, and 770 by retention time ( $0.3 \leq RT \leq 28$  min). 25 features related to ISTDs were filtered out. Out of the original 7344 features, 5211 were selected as effective metabolite candidates, from which, 193 features were identified by MS/MS libraries, 293 grouped by spectral similarity by CluMSID, and 336 by GNPS molecular networking. The colored Venn diagram shows the distribution of the 564 annotated/identified features, while the remaining 4647 features were not annotated.

Table 6.5 Feature identification based on spectral information

Identification tool	Level of information	Matches	In labeled clusters	Effective annotations <sup>a</sup>
<i>in-house</i> general	RT, MS, MS/MS	61 <sup>b</sup>		
<i>in-house</i> ( <i>P. aeruginosa</i> )	RT, MS, MS/MS	100 <sup>b</sup>	193	159 <sup>b</sup> (87 identified metabolites)
MetaboBase	<i>in-silico</i> MS/MS	15		
LipidBlast	<i>in-silico</i> MS/MS	17		
Putative	RT, MS	152 <sup>b</sup>	152	
GNPS	Experimental MS/MS	764	336	46
CluMSID	Experimental MS/MS	443	293	32

<sup>a</sup> Not sharing annotation with other identification tools

<sup>b</sup> Including manual annotation of fragments, adducts and multiply charged ions

### 6.3.3 Feature identification in negative mode

Apart from the feature filtering and identification in positive mode, a similar approach was used with data coming from the same samples analyzed in negative mode. XCMS Online and GNPS parameters were adjusted for negative mode, and the resulting data was processed in the same way as for positive mode.

From this analysis, nine features were identified by the direct match with MS/MS libraries, so their retention times, as well as *m/z* and intensity values were added to the feature table. The annotation label was preceded by “(neg)” for negative mode. As seven of them were identified as phospholipids, the corresponding class label “PhosLip” was assigned. Similarly, one feature corresponded to an alkylquinolone, therefore the class label “AQ” was assigned. However, no matches were found with the cluster analysis from GNPS and CluMSID, and no additional

putative labels were possible to assign. The annotation information is listed in Appendix VII. *Annotation table - sub-MIC ciprofloxacin concentrations.*

## **6.4 Effects of ciprofloxacin on the metabolome in fluoroquinolone-resistant and susceptible strains**

### 6.4.1 Phenotype characterization

The feature table was further analyzed to find the principal components that bring the most diversity among groups. The two components with the highest explained variance are plotted in Figure 6.9a. All samples from *gyrAparC* remain close forming a big cluster that also contains the WT untreated controls, with the exception of one replicate of the WT untreated controls, which remains far from this cluster, which can be due to experimental deviation. As expected, *gyrAparC* responded similarly to the untreated controls, as the concentrations used for the mutant have no inhibitory effect at all.

In the case of the treated WT samples, the replicates remain close to each other, but the groups with increasing antibiotic concentration are distributed along the PC1 and PC2. Since PCA is a mathematical decomposition of the possibly correlated variables within a dataset, in order to reduce its dimensionality, there is no certain way to attribute a physical variable to each component.

Additionally, a loadings plot shows what features contribute the most to the separation among the groups seen in Figure 6.9a. As shown in Figure 6.9b, rhamnolipids (in red) have the largest effect on both components, as they are located at the most distant points over both PC1 and PC2. Similarly, phenylalanine-related features (in gray) and homoserine-lactones (in purple) are gathered towards the extreme points in PC1. Alkyl-quinolones have an important effect as they are located mostly around the negative extreme of PC1; however, they are also widely distributed across the cloud of points in the plot, meaning that they have a moderate contribution to differentiate among the separated groups.

Figure 6.9 Principal component analysis of WT and gyrAparC samples treated with sub-MIC<sub>WT</sub> concentrations. a) Scores plot of PC1 and PC2 for every sample, b) loadings plot of PC1 and PC2 for every feature showing the cluster label if available. Aminoacids (AA) in aquamarine, alkyl-quinolones (AQ) in green, fatty acids (FA) in blue, glutamate (Glu) in black, glutathione (Glutathion) in yellow, homoserine-lactones (HSL) in purple, lipids (Lipid) in pink, nucleotides (Nuc) in lightgreen, phenazines (Phen) in orange, phenylalanine (Phenyl) in grey, phospholipids (PhosLip) in darkblue, rhamnolipids (Rha) in red, uridine diphosphate (UDP) in magenta.

Another method to evaluate how closely related the samples are, a correlation matrix was built with the processed and normalized data. As shown in Figure 6.7, two main clusters are indicated by the dendrogram, the first contains all the treated samples from PA14, while the second contains all the samples (treated and untreated) from PA1a gyrAparC and the untreated PA14 WT. Additionally, MIC<sub>WT</sub>-treated samples for PA14 WT form a sub-cluster, indicated by the height of the dendrogram of this group. Therefore, three main clusters are observed from left to right: I) a “high-inhibition” cluster, II) a “medium-inhibition” cluster, and III) a “non-inhibition” cluster. Furthermore, both strains PA14 WT and gyrAparC are metabolically similar, as the untreated controls are clustered together.

No surprisingly, even NIC-treated samples were included in the “inhibition” cluster, since they were delayed up to 30 min for the harvest at OD<sub>600</sub> ≈ 1.0 when compared with the untreated samples. (Table 6.3). This was previously found in the short- and long-term experiments where treatment with fluoroquinolones at NIC depicted strong responses (Figure 5.8).

Figure 6.10 Correlation matrix for PA14 WT and *gyrAparC* samples treated with  $MIC_{WT}$  and sub- $MIC_{WT}$  concentrations. Three clusters are highlighted: I) a “high-inhibition” cluster, II) a “medium-inhibition” cluster, and III) a “non-inhibition” cluster.

To this point, PA14 WT and *gyrAparC* presented different responses when treated with sub- $MIC_{WT}$  concentrations, supporting the hypothesis that the resistant strain does not respond to ciprofloxacin due to lack of binding to the target as proposed in Figure 6.1. Yet, differences in the *gyrAparC* mutant across treatment concentrations have not been identified. For this, the treated samples were compared against the respective untreated controls to find changes in abundance throughout their metabolic profiles. The log<sub>2</sub>-transformed fold changes (relative to the respective untreated controls) of identified metabolites are depicted as heat maps in Figure 6.11. A comparison between untreated samples of PA14 WT and *gyrAparC* was not carried out because both strains presented similar metabolic profiles at the harvest point.

Figure 6.11 Heat maps of identified features including their adducts (\*: putative annotation). Log<sub>2</sub>-transformed fold change (Log<sub>2</sub>FC) was calculated from the mean values of triplicates, by subtracting the log<sub>2</sub> values of each condition (I: WT\_NIC, II: WT\_IC10, III: WT\_IC50, IV: WT\_MIC, V: gyrAparC\_NIC, VI: gyrAparC\_IC10, VII: gyrAparC\_IC50, VIII: gyrAparC\_MIC) from the untreated control samples of the respective strain (WT\_CON and gyrAparC\_CON). Scaled Log<sub>2</sub>FC was performed as a default function in R Studio for visualization of over-produced metabolites (in red) and under-produced metabolites (in blue)

Generally, rhamnolipids and UDP-related metabolites showed a decrease in their intracellular abundance in both strains, indicated visually with intense blue shades in the heat maps. In the case of nucleotides, most of the decreased levels were present in PA14 WT, while *gyrAparC* presented a slight increase in their levels, indicated by light red shades. For example, WT treated samples showed less abundance of flavin adenine dinucleotide (FAD) and its precursor flavin mononucleotide (FMN), while *gyrAparC* showed slight increases. Furthermore, phenazines were consistently over-produced in both strains, and more strongly in PA14 WT treated with MIC<sub>WT</sub>, although the *gyrAparC* mutant presented slight increases in those compounds.

The panel of identified phospholipids primarily shows increased levels in PA14 WT, with particular cases for *gyrAparC*. Three phosphoethanolamines identified as PE 32:1 with 16:0 and 16:1 fatty acid chains, PE 34:1 with 16:0 and 18:1 fatty acid chains, and PE 34:2 with 16:1 and 18:1 fatty acid chains, generally increased their levels in PA14 WT, while in *gyrAparC* showed a slight increase. The levels of lyso-phosphatidylethanolamines, such as LPE 16:0, LPE 16:1 and LPE 18:1, were increased in PA14 WT, while they remained unchanged in *gyrAparC*. Additionally, the levels of the only identified phosphatidylglycerol, PG 34:2 with 16:0 and 18:1 fatty acid chains, decreased in both strains, but mainly in *gyrAparC*. Lyso-phosphatidylglycerols, such as LPG 16:0, LPG 16:1, LPG 18:1, presented higher levels in PA14 WT, while their increment in *gyrAparC* was less pronounced.

The panel of alkyl-quinolones shows great variation in the abundance of these metabolites. For instance, many PQS and QNO congeners were over-produced by PA14 WT, showing their largest change with MIC<sub>WT</sub> treatment. While the response of PA14 *gyrAparC* is less pronounced. The most abundant alkyl-quinolones C9-HQ and C9-PQS presented mild fold changes, due to the saturation in their detection, making their semi-quantitative analysis difficult. Moreover, the levels of a group of glutamate-containing metabolites, consisting mainly of glutamic acid and related peptides, were found to increase in *gyrAparC*. Finally, the levels of some fatty acids were increased in PA14 WT, while in *gyrAparC* their levels remained mostly unmodified.

Comparing the effect on WT with the effect on *gyrAparC* should disclose the target-mediated effects. From the analysis of the relative abundance of the identified features, there is evidence that some of them respond accordingly to the initial concentration used for the treatment, indicating that the intracellular metabolic response to the antibiotic exposure relates to the degree of antibiotic accumulation. The accumulation of ciprofloxacin was evaluated by the untargeted analysis and corroborated by its quantification by a targeted analysis.

## 6.4.2 Intracellular accumulation of ciprofloxacin

MS/MS identification of ciprofloxacin was carried out by direct comparison with the *in-house* library. As shown in Figure 6.12a, PA14 WT and PA14 *gyrAparC* presented a similar abundance of ciprofloxacin at  $\text{NIC}_{\text{WT}}$  and  $\text{IC}_{10\text{WT}}$ ; however, the signal was lower for PA14 WT at  $\text{IC}_{50\text{WT}}$  and  $\text{MIC}_{\text{WT}}$  compared to the mutant. Ciprofloxacin accumulation was determined by measuring the samples with the MRM targeted method for ciprofloxacin as described before for the high-throughput uptake assay (3.3.2 LC-MS/MS compound-specific MRM methods).

Figure 6.12 Ciprofloxacin accumulation determined by untargeted mode in log<sub>2</sub>-transformed area (left) and targeted mode in ng of compound in 10<sup>12</sup> CFU (right). In the untargeted method, an offset value of 50 total counts is added to all features before a logarithmic transformation, making the blank ciprofloxacin intensity in the control samples equal to 50, whose log<sub>2</sub> value is in turn equal to 5.64. In the targeted method, a blank ciprofloxacin intensity is interpolated within a standard curve, giving an actual value of 0 µg/mL.

The normalized amount of accumulated ciprofloxacin to 10<sup>12</sup> CFU is shown in Figure 6.12b, the resistant mutant *gyrAparC* exhibits a linear ciprofloxacin accumulation profile over the treatment, while the susceptible WT exhibits a logarithmic curve, reaching a plateau at  $\text{IC}_{50\text{WT}}$ . Both strains exhibit very similar accumulation profiles until  $\text{IC}_{50\text{WT}}$  concentrations, where ciprofloxacin uptake was 0.71 and 0.74 ng in 10<sup>12</sup> CFU for PA14 WT and *gyrAparC*, respectively. The picture changes for PA14 WT treated at  $\text{MIC}_{\text{WT}}$ , where ciprofloxacin uptake was 0.74 ng in 10<sup>12</sup> CFU, while in *gyrAparC* it reached 1.91 ng in 10<sup>12</sup> CFU.

During the incubation with  $\text{IC}_{50\text{WT}}$ , PA14 WT presented clump formation, indicating that *P. aeruginosa* initiates the production of biofilm even in planktonic cultures, as shown in Figure 6.13a. The optical density was measured after resuspending the bacterial clumps into the solution, but the registered values might have been affected by the biofilm formation. Thus,

information on viable cells was required. In a separate experiment, the viability of each culture at the harvest point was determined for all concentrations except for MIC<sub>WT</sub>-treated samples, since no clump formation was observed at harvest time (28 h). The determination of CFUs after antibiotic exposure revealed that the amount of viable WT bacteria is reduced across antibiotic treatment, even when bacteria were harvested at the same optical density (Figure 6.13c).

Figure 6.13 a) Visual phenotyping of PA14 WT control and after exposure to IC50WT of ciprofloxacin, b) optical density to the harvest point, c) viable bacteria harvested at OD<sub>600</sub> = 1.0 under treatment with sub-MIC concentrations

#### 6.4.3 Responsive features to ciprofloxacin accumulation

As shown before in Figure 6.11, some of the features from the untargeted analysis respond accordingly with the initial concentration used for the treatment. To investigate which features respond to the treatment in each strain, a Spearman correlation between the corresponding ciprofloxacin feature and each of the rest of the features was computed independently for PA14 WT and PA14 gyrAparC. In 2017, Zampieri *et al.* proposed a procedure where metabolites showing responses that change proportionally (or inverse proportionally) to a low and a high concentration of antibiotic were selected as responsive metabolites (Zampieri *et al.* 2017). A similar concept is proposed in this study, where the features that respond similarly to the degree of antibiotic exposure were selected as responsive features.

Each strain exhibits a different correlation profile as shown in the U-plots in Figure 6.14, where the compound class identified by clustering tools is displayed. PA14 WT generates a broader U-plot with more significantly correlated points compared with gyrAparC, indicating that the susceptible WT responds more readily to the presence of the antibiotic, although the nature of the responsive features in WT and gyrAparC varies greatly. To provide a better view of the responsive features to ciprofloxacin treatment, Figure 6.15 depicts bar plots of only identified features that show a significant correlation with ciprofloxacin uptake.

Direct and indirect responses upon antibiotic exposure

Figure 6.14 U-plots of feature correlation with ciprofloxacin accumulation in PA14 WT and in PA14 gyrAparC. Annotation of the identified features (\*: putative annotation) is shown in black, and the compound class identified by clustering tools is shown in red. For each feature, the Spearman correlation with ciprofloxacin levels in all conditions was performed and the corresponding p-value was calculated. Dots in green:  $0.5 \leq \text{correlation} \leq -0.5$  &  $p\text{-value} \leq 0.05$ , dots in purple:  $0.8 \leq \text{correlation} \leq -0.8$  &  $p\text{-value} \leq 0.01$

Figure 6.15 Bar plots of identified features (\*: putative annotation) showing a significant correlation ( $0.5 \leq \text{correlation} \leq -0.5$  &  $p\text{-value} \leq 0.05$ ) with ciprofloxacin uptake in PA14 WT (left), in PA14 gyrAparC (right). Alkyl-quinolones in green, fatty acids in blue, glutamate in black, glutathione in yellow, homoserine-lactones in purple, nucleotides in lightgreen, phenazines in orange, phospholipids in darkblue, rhamnolipids in red, uridine diphosphate in magenta.

## 6.4.3.1 Commonly responsive features

As shown in Figure 6.15, some features responded similarly in both strains, indicating that the alteration of their abundance is not a result of growth inhibition, but rather a general response due to diverse interactions with the compound.

Metabolites involved in the quorum-sensing mechanisms of *P. aeruginosa* responded positively to ciprofloxacin treatment. The identified homoserine lactones N-butanoyl-homoserine lactone (C4-HSL) and N-(3-Oxododecanoyl)-L-homoserine lactone (3-oxo-C12-HSL) correlated strongly positively to ciprofloxacin in PA14 WT, while in PA14 *gyrAparC* 3-oxo-C12-HSL showed a moderate correlation with a significant fold-change at MIC<sub>WT</sub> (Figure 6.16).

Figure 6.16 Box plots of identified homoserine lactones C4-HSL and 3-oxo-C12-HSL. Significance was calculated by Student's T-tests of each condition against the untreated control: \*\*\* for p-value  $\leq 0.001$ , \*\* for  $0.001 < \text{p-value} \leq 0.01$ , \* for  $0.01 < \text{p-value} \leq 0.05$

Alkyl-quinolones responded positively in both PA14 WT and PA14 *gyrAparC* (Figure 6.15). In WT, 2-alkyl-4-quinolones (-HQ), 2-alkyl-3-hydroxy-4-quinolones (-PQS) and 2-alkyl-hydroxyquinoline-N-oxides (-QNO) followed a direct correlation with ciprofloxacin, while in PA14 *gyrAparC* the most directly correlated features were identified as long-chain-HQ congeners (C11-C17). As shown in Figure 6.17a, the levels of DHQ, C7-HQ and C7-PQS also showed an increase in PA14 *gyrAparC*.

Figure 6.17 Box plots of identified intermediates and final products in the phenazine and PQS biosynthetic pathway: a) anthranilate, DHQ, HHQ (C7-HQ) and PQS (C7-PQS), b) phenazine-1,6-dicarboxylic acid, phenazine-1-carboxylic acid, phenazine, pyocyanin and 1-hydroxyphenazine. Significance was calculated by Student's T-tests of each condition against the untreated control: \*\*\* for  $p$ -value  $\leq 0.001$ , \*\* for  $0.001 < p$ -value  $\leq 0.01$ , \* for  $0.01 < p$ -value  $\leq 0.05$ . PQS pathway starts from chorismate towards the conversion to anthranilate, while phenazine pathway starts from chorismate towards the conversion to 2-amino-4-desoxyisochorismate by phzE (<https://www.genome.jp/kegg/kegg1.html>)

Phenazines levels correlated directly to ciprofloxacin accumulation, although the intermediates showed to be more responsive to PA14 WT. As shown in Figure 6.17b, the end products of the biosynthetic pathway were increased in both strains according to ciprofloxacin treatment, but PA14 WT showed the most significant changes when compared with the untreated controls. Particularly, the levels of phenazine-1-carboxylic acid, pyocyanin and 1-hydroxyphenazine showed significant changes in WT even when treated at  $NIC_{WT}$ .

Conversely, rhamnolipids correlated negatively to ciprofloxacin uptake in both strains. In Figure 6.15, mono-rhamnolipids showed a negative correlation in PA14 but not di-rhamnolipids. However, the box plots in Figure 6.18 show that the abundance of mono- and di-rhamnolipids increased back substantially when PA14 WT was treated with  $MIC_{WT}$ , in converse order to the concentration-dependent reduction of abundance at sub- $MIC_{WT}$  concentrations. On the other hand, in PA14 *gyrAparC*, rhamnolipids followed a decreased abundance along with ciprofloxacin treatment.

Figure 6.18 Box plots of identified rhamnolipids a) mono-rhamnolipids, b) di-rhamnolipids. Significance was calculated by Student's T-tests of each condition against the untreated control: \*\*\* for  $p$ -value  $\leq 0.001$ , \*\* for  $0.001 < p$ -value  $\leq 0.01$ , \* for  $0.01 < p$ -value  $\leq 0.05$

Furthermore, the levels of identified lipids and phospholipids were responsive to ciprofloxacin uptake in both strains (Figure 6.15). Specifically, lyso-phosphatidylglycerols LPG (16:0) and LPG (18:1), and lyso-phosphatidylethanolamines LPE 16:0, LPE 16:1, LPE 17:1 and LPE 18:1 responded positively to ciprofloxacin uptake. Conversely, phosphatidylglycerol PG 34:1 correlated inversely, while phosphoethanolamine PE 34:1 did not have a clear trend and PE 34:2 increased in WT. Some fatty acids such as lauric acid (C12:0), elaidic acid (C16:1), palmitate (C16:0) and palmitoleic acid (C16:1) were also directly correlated with ciprofloxacin

uptake. Generally, PA14 WT showed the most significant changes when compared with the untreated controls. Additionally, pyochelin and glutamic acid correlated directly to ciprofloxacin uptake. Moreover, L-2-phosphoric acid correlated inversely in PA14 WT, while in PA14 *gyrAparC* it showed a generally decreased abundance.

UDP-MurNAc-pentapeptide adducts were the most inversely correlated features in PA14 WT, although they also showed a correlation in PA14 *gyrAparC* (see Figure 6.15). UDP-MurNAc-pentapeptide is the last intermediate of the reaction that is still unbound to a membrane-embedded scaffold, and it is still free in the cytoplasm (for details, see Figure 1.2). Because the metabolomics workflow was optimized for the extraction of metabolites with medium polarity, none of the subsequent intermediates of peptidoglycan assembly were available for LC-MS/MS detection.

Figure 6.19 Box plots of UDP-MurNAc-pentapeptide. The doubly protonated molecular ion  $[M+2H]^+$  was presented higher abundance than the singly protonated ion. Significance was calculated by Student's T-tests of each condition against the untreated control: \*\*\* for  $p\text{-value} \leq 0.001$ , \*\* for  $0.001 < p\text{-value} \leq 0.01$ , \* for  $0.01 < p\text{-value} \leq 0.05$

#### 6.4.3.2 Responsive features in PA14 WT

Furthermore, some nucleotides such as adenosine monophosphate (AMP), adenosine diphosphate (ADP), flavine mononucleotide (FMN), flavine adenine dinucleotide (FAD), and nicotidamide adenine dinucleotide phosphate (NADP<sup>+</sup>) correlated inversely (Figure 6.15). Conversely, the levels of glutathione in PA14 WT correlated positively with ciprofloxacin uptake. Additionally, 86 unidentified features showed a strong correlation with ciprofloxacin uptake ( $0.8 \leq \text{correlation} \leq -0.8$ ). Three of the unidentified correlated features were assigned with a label for alkyl-quinolones, and one for glutamate-related compounds, but they were not identified manually by exact mass nor MS/MS spectral information (Table 6.6).

Direct and indirect responses upon antibiotic exposure

The fact that two of the AQ-labeled features have an odd m/z value indicates that they do not correspond to an alkyl quinolone structure (containing one nitrogen atom), as their nominal mass is an even number as a protonated species, and that would violate the “nitrogen rule” (Watson and Sparkman 2007). On the contrary, the Glu-labeled feature seems to be in agreement with the nitrogen rule, as its odd m/z value could correspond to a dipeptide (containing two nitrogen atoms).

## 6.4.3.3 Responsive features in PA14 gyrAparC

In general, most of the responsive features in PA14 gyrAparC were also found to respond to PA14 WT, although to a different extent. As shown before in Figure 6.18, rhamnolipids were found to correlate more strongly in PA14 gyrAparC than in WT. Additionally, some nucleotides such as N-acetylglucosamine and NAD were found to correlate positively only in PA14 gyrAparC. However, 12 additional features showed a strong correlation with ciprofloxacin uptake ( $0.8 \leq \text{correlation} \leq -0.8$ ) only in PA14 gyrAparC but not in WT (Table 6.7). One of the unidentified correlated features was assigned as an alkyl-quinolone, but it was not identified manually by exact mass nor MS/MS spectral information. Again, the AQ-labeled feature has an odd m/z value, which indicates that it does not correspond to an alkyl quinolone structure.

Table 6.7 Features with high correlation to ciprofloxacin uptake in PA14 gyrAparC

Feature name	Retention time	m/z value	Correlation	Compound class	Feature name	Retention time	m/z value	Correlation	Compound class
M150T1	1.16	150.1126	0.8561		M458T25	25.42	458.3534	0.8186	
M282T15_2	15.36	282.2799	0.8382		M227T1_1	1.31	227.0545	0.8168	
M783T22	22.09	783.1846	0.8311		M328T13_1	12.97	328.1426	0.8132	
M310T17_2	16.83	310.3104	0.8240		M310T17_3	17.41	310.3301	0.8079	
M635T23	23.20	634.8760	0.8240		M309T17_2	17.41	309.3268	0.8025	AQ
M423T1_2	1.22	423.0650	0.8190		M298T11_2	11.00	298.2018	-0.8079	

While PA14 WT showed significant changes in many of the analyzed features with respect to the untreated control, PA14 gyrAparC showed modest log<sub>2</sub>-fold changes visually perceptible, but marginally significant with respect to the untreated control. The fact that the correlation of the described identified features to ciprofloxacin accumulation is significant ( $p\text{-value} \leq 0.05$ ) does not necessary guarantee that the levels of those features were significantly changed at each treatment concentrations with respect to the untreated controls. Therefore, in order to find the most responsive features to ciprofloxacin treatment, a volcano plot of gyrAparC treated with MIC<sub>WT</sub> compared with the untreated control is shown in Figure 6.20.

Figure 6.20 Volcano plot of *gyrAparC* treated at  $MIC_{WT}$  compared with the untreated control, showing the identified features (\*: putative annotation). Significance: purple dots:  $-2 \leq \log_2FC \leq 2$  and  $p\text{-value} \leq 0.01$ , green dots:  $-1 \leq \log_2FC \leq 1$  and  $p\text{-value} \leq 0.05$ .

The *gyrAparC* mutant treated with the highest concentration of  $0.151 \mu\text{g/mL}$  presented mainly over-produced metabolites when compared to the untreated control. The volcano plot revealed 135 over-produced features, and 32 less produced features (Figure 6.20). In consistency with the correlation analysis in Figure 6.14 and Figure 6.15, long-chain alkyl-quinolones were over-produced significantly upon treatment with  $MIC_{WT}$ . The protonated ions of C15:1-HQ, C17:1-HQ and C12:0-HQ, as well as their adducts, were significantly over-produced.

The difference in abundance of the most significantly regulated metabolites is better displayed as box plots in Figure 6.21, even if not all of them were highlighted in the volcano plot. Five of the identified long-chain alkyl-quinolones from C11 to C17 presented a significant increase in abundance. Interestingly, the longer the alkyl-chain of these metabolites, the most significant their over-production.

Figure 6.21 Box plots of most significantly regulated features in *gyrAparC* treated at  $MIC_{WT}$  compared with the untreated control, showing only the singly-protonated species and not their adducts. Significance was calculated by Student's T-tests of each condition against the untreated control: \*\*\* for  $p$ -value  $\leq 0.001$ , \*\* for  $0.001 < p$ -value  $\leq 0.01$ , \* for  $0.01 < p$ -value  $\leq 0.05$

Additionally, other metabolites such as pyochelin, 3-oxo-C12-HSL, and LPG (identified in negative mode) were found to be significantly over-produced in  $MIC_{WT}$  treated samples (Figure 6.21). On the other hand, Rha-C10-C12 and C9-QNO were less produced after the treatment.

As a summary, the responses of WT and *gyrAparC* mutant, listed in Table 6.8, differentiate the secondary effects of ciprofloxacin accumulation. PA14 WT treated with sub-MIC and MIC concentrations of ciprofloxacin showed growth inhibition, biofilm production, and an increased oxidative-stress response, attributed to the effect of ciprofloxacin acting on its main target *gyrA*. In contrast, the *gyrAparC* mutant did not show any growth inhibition nor biofilm production, even though ciprofloxacin accumulated to the same and higher extent than in PA14 WT, indicating that the main target *gyrA* was unaffected. Up to a different extend, both strains produced less rhamnolipids when exposed to ciprofloxacin, and they both showed higher levels of QS molecules, such as alkyl-quinolones and homoserine lactones. In general, the peptidoglycan assembly of both strains was affected, as well as the lipid metabolism.

Table 6.8 The response of *P. aeruginosa* WT and gyrAparC mutant to ciprofloxacin treatment at sub-MIC and MIC concentrations

<b>Response</b>	<b>WT</b>	<b>gyrAparC</b>
Growth inhibition	Yes	No
Biofilm formation	Yes	No
Target binding	Yes	No
Compound accumulation	Yes	Yes
Oxidative-stress response	Increased	No change
Rhamnolipid production	Decreased	Decreased
Lipid metabolism	Altered	Altered
Peptidoglycan assembly	Altered	Altered
QS response	Increased	Increased

The previous analysis verifies the hypothesis formulated in Figure 6.1, demonstrating that *P. aeruginosa* presents an alternative response to the accumulation of ciprofloxacin, attributed only to secondary target effects.

## 6.5 Discussion

### **Ciprofloxacin accumulates to the same extent in resistant and sensitive *P. aeruginosa* at sub-MIC concentrations, but not at MIC**

The fact that introducing two-single mutations in *gyrA* T83I and *parC* S87L confers PA14 with substantial resistance to ciprofloxacin does not affect intracellular compound accumulation. In fact, the accumulation of ciprofloxacin in the resistant and susceptible strains does not correlate with their fold change of inhibitory concentrations. Although the point mutations increase the values of sub-MIC concentrations by more than 8 log<sub>2</sub>-units, ciprofloxacin accumulated to the same extent in both the sensitive WT and the resistant strain PA14 *gyrAparC*.

Ciprofloxacin has been reported to induce biofilm formation at concentrations below MIC (Linares et al. 2006; Morita, Tomida, and Kawamura 2014). Consistent with the literature, at IC<sub>50</sub> PA14 WT started biofilm production and clump formation, which was also observed at MIC. The effects of biofilm-based antibiotic resistance and tolerance have been extensively studied and a complete revision has recently been published (Hall and Mah 2017). The literature suggests that the reduced susceptibility to certain antibiotics may be influenced by the diffusion limitation through biofilms. In particular, ciprofloxacin has been found to successfully penetrate experimental biofilms setups (Hall and Mah 2017). In the present study, the values of accumulated ciprofloxacin increased along with the increasing concentration until reaching a plateau at the concentration when biofilm was observed. The same levels of intracellular ciprofloxacin were found at IC<sub>50</sub> and MIC, indicating that clump formation could act as a protective measure to restrict the surface contact of bacteria with the solubilized compound. It is important to note that biofilm formation was not observed in the untreated controls after 7h of incubation in BM2 medium with casaminoacids, in agreement with previous reports where biofilms are developed after 24 h in tryptic soy broth (Pericolini et al. 2018) or after three days in Muller Hinton medium (Al-kafaween et al. 2019).

Nevertheless, the stationary compound accumulation cannot be attributed to biofilm formation alone. The coordinated response of bacteria to decrease porin expression and increase the efflux capability is known to reduce the net permeability in the outer membrane (Fernández and Hancock 2012). But although *P. aeruginosa* is capable of exporting fluoroquinolones by four of its known efflux pumps: MexCD-OprJ, MexEF-OprN, MexAB-OprM, and MexXY-OprM (Nakajima et al. 2002; Fernández and Hancock 2012), there is no evidence that ciprofloxacin itself acts as a regulator for their over-expression. However, ciprofloxacin does promote the formation of ROS in susceptible *P. aeruginosa*'s strains (but not in *gyrA* resistant mutant)

(Jensen et al. 2014), and oxidative stress has been found to induce the genes that code for MexXY in *P. aeruginosa* (Fraud and Poole 2011).

The fact that PA14 maintains the same levels of ciprofloxacin accumulation in both the sensitive and the resistant strain under sub-MIC<sub>WT</sub> concentrations suggests that the synergistic effect of active compound efflux and biofilm production in the susceptible WT occurs at a certain compound concentration threshold (IC50<sub>WT</sub> in the present study). However, more studies are required to differentiate the compound concentration dependence of both biofilm and ROS production, e.g. the study of the transcriptome in a concentration-dependent manner, while monitoring the formation of hydroxyl radicals may give insights into the expression levels of efflux genes and biofilm production genes.

### **On-target metabolic effects of ciprofloxacin**

Fluoroquinolones are known to propitiate bacterial responses in *P. aeruginosa*, such as biofilm formation, diminished swimming and swarming, induction of SOS response, up-regulation of the bacteriophage-like pyocins (Morita, Tomida, and Kawamura 2014). Most of these responses are associated with the result of the compound's interaction with the protein target.

Since ciprofloxacin is known to produce oxidative stress in bacteria (Becerra and Albesa 2002; Wu et al. 2012), it is not surprising to find elevated levels of oxidized glutathione, which serves as a preventive antioxidant in the presence of ROS. Similarly, phenazine production increased with ciprofloxacin uptake in PA14 WT. Phenazines are redox-active molecules, and among other functions, they modify the cellular redox state (Pierson and Pierson 2010). However, their over-production would be deleterious for the bacterial cells because they induce the generation of ROS. Therefore, phenazines should have a different role than keeping the redox intracellular homeostasis in PA14 WT. Phenazines have an important impact on biofilm architecture and cell adhesion (Pierson and Pierson 2010), and the results of this study suggest that biofilm is enhanced at increasing concentrations of ciprofloxacin.

One metabolite that showed the most dependence with ciprofloxacin uptake was UDP-MurNac-pentapeptide. At first glance, its decreasing amount indicates a compromised turnover of the peptidoglycan wall. However, Jedrey *et al.* recently found that PAO1 WT treated with sub-MIC concentrations (50 and 75 ng/mL) of ciprofloxacin increased its modulation of the UDP-MurNac-tripeptide synthetase *murE*, but not its *gyrA* resistant strain (Jedrey, Lilley, and Welch 2018). Furthermore, when Lipid II is modified and then translocated to the outer leaflet of the cytoplasmic membrane, a driving force in the cytoplasm is generated to favor its biosynthesis, accelerating the substrate consumption in the up-stream cascade. Together,

these observations suggest that the peptidoglycan assembly is generally enhanced as an effect of ciprofloxacin activity.

Induction of the SOS response has been shown to induce persister cells under sub-MIC treatment with ciprofloxacin (Dörr, Lewis, and Vulić 2009; Andersson and Hughes 2014; Johnson and Levin 2013). Persisters tend to grow very slowly or tend to emerge stochastically after non-growing conditions, providing them with a low metabolic state though to be responsible for surviving to antibiotic exposure (Brauner et al. 2016).

In this study, PA14 WT was incubated for 28 hours at MIC, having enough time to develop a drug-tolerant phenotype of persister cells. Although the study of the persister phenotype was not among the goals of this project, it was found that the levels of some metabolites in PA14 WT treated at MIC responded in a different manner than the rest of the treatment concentrations.

#### **Off-target metabolic effects of ciprofloxacin**

Quorum sensing molecules were found to be highly responsive in both the susceptible and the resistant strain, posing a great interest as many virulence factors in *P. aeruginosa* are regulated by quorum sensing. PA14 gyrAparC showed a ciprofloxacin-dependent increase in long-chain AQs. The diversity of the acyl chain of AQs depends on the available pool of acyl-CoA for AQ biosynthesis, and in turn, on the available pool of fatty acids (Witzgall et al. 2018). The over-production of long-chain AQs suggests that the pool of fatty acids that is available for AQ biosynthesis was unbalanced by the presence of the antibiotic.

More evidence supports the idea of an alteration in the lipid pool. On the one hand, the rhamnolipid biosynthetic pathway shares one acyl-CoA substrate (octanoyl-CoA) with the AQ pathway, and their abundance decreased along with ciprofloxacin uptake. On the other hand, LPEs and LPGs, which are involved in lipid metabolism, were responsive in PA14 gyrAparC and their abundance increase along with ciprofloxacin concentration.

Although, additional efforts to identify important responsive features are still required to conceive a complete picture of the indirect effects of compound accumulation, the analysis of the identified features gives already valuable information on the off-target interactions of ciprofloxacin in *P. aeruginosa* (see Table 6.9).

Table 6.9 On- and off-target effects of ciprofloxacin accumulation in *P. aeruginosa*

On-target effects	Off-target effects
Growth inhibition	Intracellular antibiotic accumulation
Target binding	Decrease in rhamnolipid production (Rha ↓)
Biofilm formation	Elevated QS response (AQs ↑, HSL ↑)
Elevated oxidative-stress response (GHS ↑, Phen ↑)	Alteration in lipid metabolism (PG ↓, LPG ↑, LPE ↑, LC-AQs ↑)
	Affected peptidoglycan assembly (UDP-MurNac-pentapeptide ↓)

AQs: alkyl-quinolones, GHS: glutathione, HSL: homoserine lactones, LC: long chain, LPE: lyso-phosphatidylethanolamines, LPG: lyso-phosphatidylglycerols, PG: phosphatidylglycerol, QS: quorum sensing, Rha: rhamnolipids.

The results in this study support the theory that antibiotics act as stress inducers when growth inhibition is achieved, and they act as cues in the absence of inhibition (Bernier and Surette 2013). While it is true that fluoroquinolones are “sensed” by *P. aeruginosa* and they exert a preparatory bacterial response, they do not act as signaling molecules as they are not considered autoinducers (Diggle et al. 2007). However, fluoroquinolones enhanced the QS system in an intracellular concentration-dependent manner, leaving the open question of a possible secondary target, or targets, until now unknown.

## CONCLUDING REMARKS AND OUTLOOK

This study tackled two of the main aspects in the struggle against the increasingly frequent antibiotic resistance: the capability of bacteria to accumulate antibiotics and their response to insufficient amounts of compound needed to arrest growth.

Detecting and quantifying the small amounts of antibiotics accumulated in susceptible bacterial cells is challenging, and powerful analytical techniques are required. Here, an LC-MS/MS-based assay was developed, optimized and applied to measure the absolute and dynamic accumulation of antibiotics with different modes of action into *E. coli* and *P. aeruginosa*, showing different accumulation profiles in spite of both being Gram-negative. One advantage of the assay is its strain transferability and its medium-high throughput, since it allows the systematic assessment of the accumulation of a broad range of compounds in different microorganisms. As it is a compound-specific LC-MS/MS method, it could allow the direct detection of possible intracellular modifications occurring on the compounds after their uptake, e.g. hydrolyzed  $\beta$ -lactams or modified aminoglycosides.

With respect to the response to sub-lethal concentrations of antibiotics, the metabolic profile of wild type *P. aeruginosa* treated with different classes of antibiotics showed important differences in the response profiles under short and long exposure. As a quick response to sudden antibiotic stress, *P. aeruginosa* maintained high levels of virulence-related metabolites, such as rhamnolipids.

Additionally, this study provided new insights into the off-target effects of *P. aeruginosa* treated with sub-lethal concentrations of ciprofloxacin. The metabolic profiles of a susceptible and a resistant strain, with MIC values of 0.15  $\mu\text{g}/\text{mL}$  and 29.83  $\mu\text{g}/\text{mL}$ , respectively, provided evidence of indirect responses to increasing concentrations of ciprofloxacin. The resistant mutant showed important off-target effects in response to ciprofloxacin accumulation, despite the lack of activity of the compound to the target.

An open question remains about the behavior of sensitive strain incubated at MIC (determined on a plate assay), where the trend on the response of certain metabolites to compound accumulation was disrupted. A methodological evaluation of the presence and behavior of persister cells at such conditions is still needed, as persister cells are likely to emerge under the culture conditions (28h at 37°), and they are metabolically different from the otherwise susceptible cells, and the current analysis is suited for homologous cultures.

The use of untargeted metabolomics studies provided information on the nature of the found off-target effects, which were related to the complex quorum sensing network in *P. aeruginosa*. The study of small sensing molecules is a good example of the applicability of metabolomics, although the effects on the regulatory system can be reconstructed at the transcriptome level. It is common to make use of more than one of the “omics” technologies for comprehensive analyses, where efforts must be made to preserving the experimental conditions across the different workflows. On the same basis, analyzing the transcriptome response can enable identifying possible secondary targets of fluoroquinolones in *P. aeruginosa*'s resistant strains, in order to complement the current knowledge on sensitive strains.

Furthermore, alterations in lipid metabolism were consistently found as a result of fluoroquinolone treatment. Lipid metabolites were dysregulated not only during under short or long exposure of wild type *P. aeruginosa* to ciprofloxacin and levofloxacin, but also under the exposure of the resistant mutant to increasing concentrations of ciprofloxacin. Further studies on lipidomic analysis could contribute to clarify the extent of such alterations as a result of antibiotic activity in the wild type, and off- target-related response in the resistant mutant.

## II. Extractables from filter-plate-based metabolomics workflow

Figure A1. TIC of one untreated sample showing the 19 peaks coming from the filter plates (above), where the intrametabolome was extracted with 80% MeOH. Adjacent peaks from 1-9 have a difference in  $m/z$  values of 44.026 from the most abundant singly-charged ion, and from peaks 10-19 the  $m/z$  difference is 22.014, from the doubly-charged ions, shown in the average mass spectrum of the 19 peaks (below). Adjacent peaks with a difference in 44 Da show typical mass distribution of polyethylene glycol (PEG)

Table A2. Most abundant features found in the peaks coming from the filter plates. Intensity values are the average of all samples (n=48)

Peak	RT (min)	m/z	Adduct	Mean Log2 intensity	CV (%)

#### IV. MS and MS/MS identification

2-Hydrophenazine (RT, MS, MS/MS):

3-oxo-C12-HSL (RT, MS, MS/MS):

ADP and ADP [M+Na]<sup>+</sup>:

AMP (RT, MS, MS/MS):

C7-QNO:

C7-PQS:

C7:1-PQS

C8-QNO (RT, MS, MS/MS):

C6:-HQ (RT, MS, MS/MS):

C7:1-HQ (RT, MS, MS/MS):

C9-QNO (RT, MS, MS/MS):

C9:1-HQ (RT, MS, MS/MS):

C9:1-QNO (RT, MS, MS/MS):

C11:0-PQS

C11:0-PQS

Not a AQ

Ciprofloxacin

DHQ (RT, MS):

NAD (RT, MS, MS/MS):

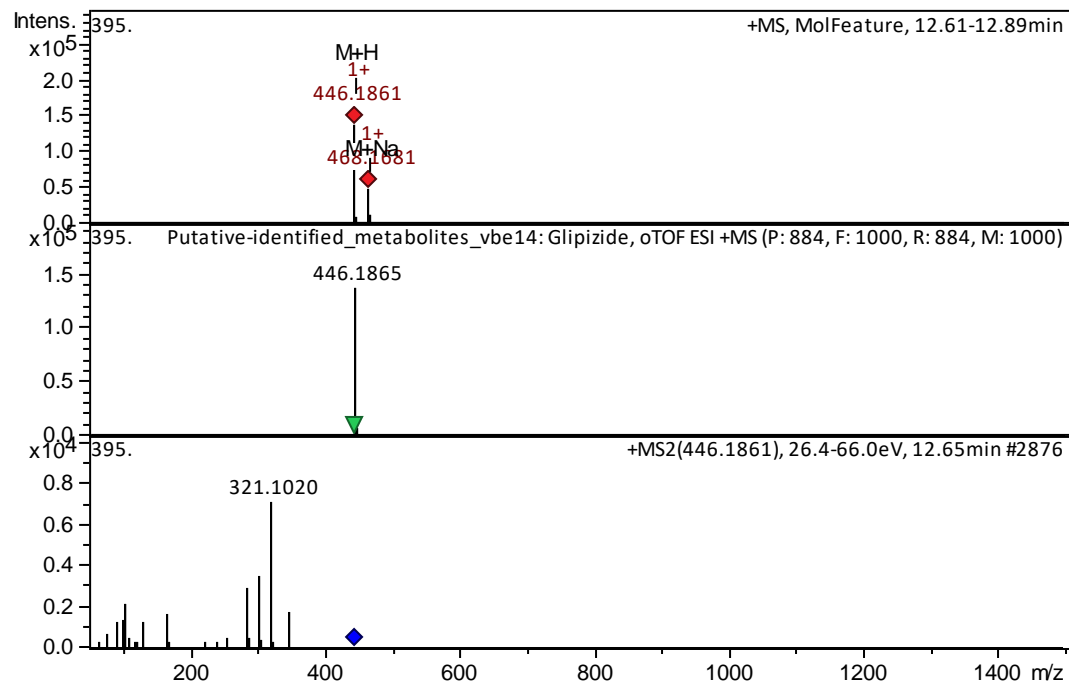

Ethanolamine phosphate (RT, MS, MS/MS)

Erucic acid (RT, MS, MS/MS):

Glipizide (RT, MS, MS/MS):

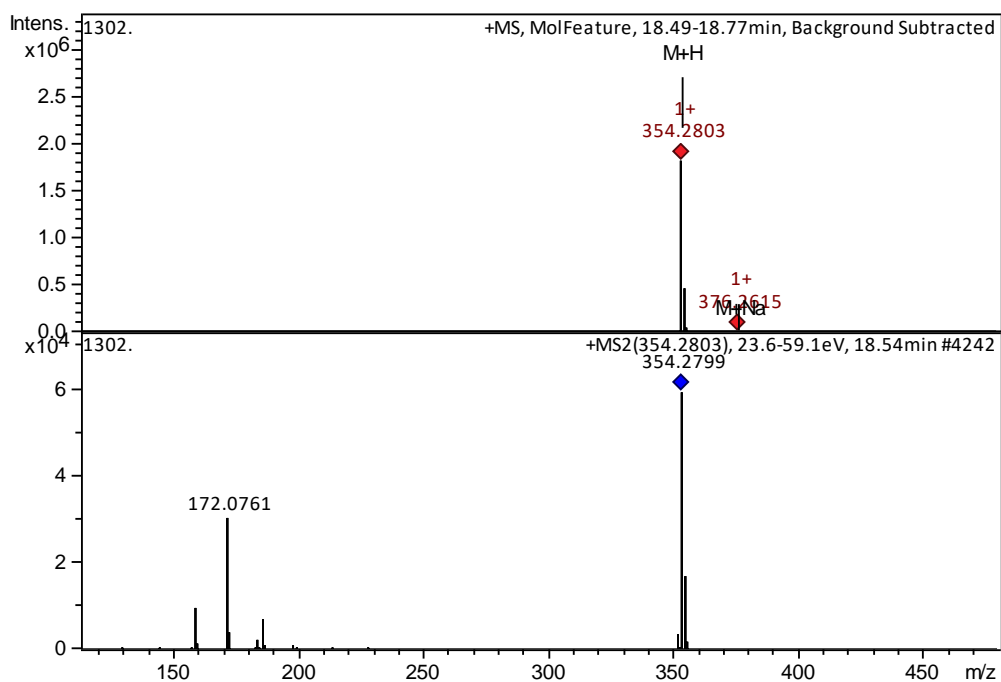

Gluthathion (RT, MS, MS/MS):

An AQ

C15:1-HQ

Rha-C10-C12:1+Na

Hydroquinone:

Pinolenic acid (RT, MS, MS/MS):

Palmitoleic acid (RT, MS):

Tryptophan (RT, MS, MS/MS):

Glucose (RT, MS):

Glucose-phosphate (RT, MS)

Glutamic acid (RT, MS, MS/MS):

Hydroxy-phenazine-1-carboxylic acid (RT, MS):

Phenazine-1-carboxamide (RT, MS, MS/MS):

Phenazine (RT, MS):

Pyochelin (RT, MS):

UDP-MurNAc-pentapeptide (RT, MS):

UDP-GlcNAc (RT, MS, MS/MS):

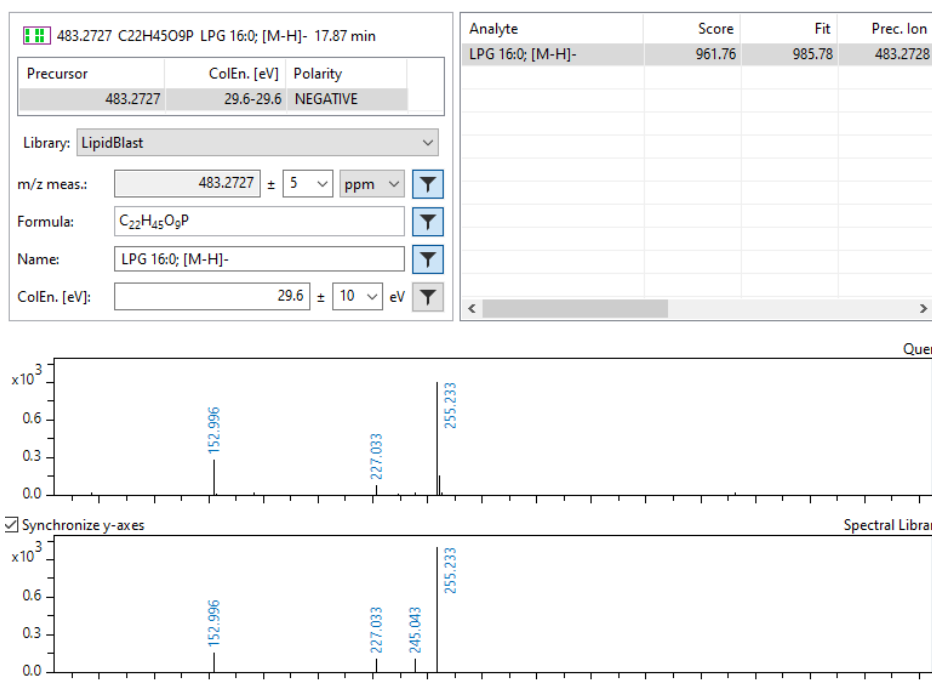

Spermidine (RT, MS, MS/MS):

LPE 16:0 (RT, MS, MS/MS)

LPE 16:0 (RT, MS, MS/MS)

PG 34:1 (RT, MS, MS/MS)

## VII. Annotation table - sub-MIC ciprofloxacin concentrations

Table A12. Annotation table of metabolomics experiments upon treatment at sub-MIC and MIC concentrations. \*:Putative label, AA: amino acids, AQ: alkylquinolones, FA: fatty acids, Glu: glutamate-related, Gluc:glucose, HSL: homoserine lactones, Nuc: nucleotides, Phen: phenazines, Phenyl: phenylalanine, PhosLip: phospholipids, Rha: rhamnolipids, UDP: uridine phosphate-related

## **ACKNOWLEDGEMENTS**

I would like to thank my PhD supervisor, Prof. Mark Brönstrup, for giving me the opportunity to carry out my research under his guidance in the Chemical Biology group at HZI. Also to the members of my Thesis Committee, Prof. Susanne Häußler and Prof. Lothar Jänsch, for their valuable feedback and important ideas along my PhD time. Thanks to Prof. Häußler for kindly donating the mutant strain for my research.

Many thanks to the Metabolomics subgroup of CBIO, Tobias Depke, Volker Berndt, Federica Fiorini, Aamna Habib, Katharina Rox, Heike Overwin, who made my everyday work in the lab more enjoyable, and from whom I learned a lot. Special thanks to Raimo Franke for all the fruitful discussions, criticism and pep talks along my time in CBIO, and to Prof. Ursula Bilitewski for her encouragement.

I would also like to thank my colleagues Aditya Shekhar, Jana Krull, Charlotte Grandclaudon, Yi-Hui Lai, and Hans Prochnow, for the many laughs and good experiences that filled my days with joy and made my stay a great experience.

Thanks a lot to Hazel Fuchs, and Raimo for helping me with a peer review of my thesis, and I would like to thank all the other members of CBIO, who I have not listed individually here, for making my stay at CBIO a learning and growth experience.

I would also like to thank Prof. Alejandro León Galicia because his words are with me all the time, even in times of doubt. Thanks to my family for their support, and for being close even in the distance, and to my husband for his encouragement and enthusiasm in this journey that we started together.

## CURRICULUM VITAE

### Maríel Anel García Rivera

#### Personal information

Date of birth: 05.03.1989

Place of birth: Mexico City

#### Education

03/2016 – present  
**Helmholtz-Zentrum für Infektionsforschung (HZI)**  
**PhD in Chemical Biology**  
Braunschweig, Germany

- Expertise: Mass spectrometry, detection of small molecules, metabolomics, chemometrics, Data Mining
- PhD Thesis: “Antibiotic uptake in *Pseudomonas aeruginosa* and its consequences on the metabolome”
- Supervisor: Prof. Dr. rer. nat. Mark Brönstrup (Leibniz Universität Hannover and HZI)

09/2013 – 10/2015  
**École Polytechnique Fédérale de Lausanne (EPFL)**  
**M.Sc. in Chemical Engineering and Biotechnology**  
Lausanne, Switzerland

- Expertise: Biotechnology, Process Development, Green Chemistry
- Master thesis: “Investigation of an integrated separation-racemization process for the production of enantiomerically pure mandelic acid”
- Supervisors: Hon.-Prof. Albert Renken (EPFL), Prof. Dr.-Ing. Andreas Seidel-Morgenstern (Max-Planck-Institute für Dynamik komplexer technischer Systeme, Magdeburg)

09/2006 – 04/2012  
**Universidad Autónoma Metropolitana (UAM),**  
**B.Sc. in Chemical Engineering**  
Mexico City, Mexico

- Expertise: Process Development, Quality Systems, Environmental sustainability
- Bachelor thesis: The effect of hydraulic variables on the adsorption of phenol on activated coal
- Supervisors: Prof. Alejandro León Galicia (UAM), Prof. Alethia Vázquez Morillas (UAM)
