Heterologous expression of the avirulence gene 

**ACE1** from the fungal rice pathogen *Magnaporthe oryzae*†

The **ACE1** and RAP1 genes from the avirulence signalling gene cluster of the rice blast fungus *Magnaporthe oryzae* were expressed in Aspergillus oryzae and *M. oryzae* itself. Expression of **ACE1** alone produced a polyenyl pyrone (magnaporthepyrone), which is regioselectively epoxidised and hydrolysed to give different diols, 6 and 7, in the two host organisms. Analysis of the three introns present in **ACE1** determined that *A. oryzae* does not process intron 2 correctly, while *M. oryzae* processes all introns correctly in both appressoria and mycelia. Co-expression of **ACE1** and RAP1 in *A. oryzae* produced an amide 8 which is similar to the PKS-NRPS derived backbone of the cytochalasan. Biological testing on rice leaves showed that neither the diols 6 and 7, nor amide 8 was responsible for the observed **ACE1** mediated avirulence, however, gene cluster analysis suggests that the true avirulence signalling compound may be a tyrosine-derived cytochalasan compound.

**Introduction**

The rice blast fungus *Magnaporthe oryzae*, which causes significant reductions in rice yields,1 is a well-known model for studying plant fungal interactions and pathogenicity.2 Rice resistance receptors (R) recognize *M. oryzae* secreted avirulence signals (AVR), allowing the rice plant to mount an effective defence response, killing or containing the fungus within the initial infected cell. Genetic and molecular studies have conclusively linked the avirulent phenotype of strain Guy11 on rice cultivars carrying the resistance gene *Pi33*, to the presence of the **ACE1** gene (Avirulence Confering Enzyme).3,4 Unlike the majority of known AVR genes which encode small secreted proteins acting directly on the host plant,5 **ACE1** encodes a cytoplasmic biosynthetic protein responsible for the production of a low molecular weight compound.6

**ACE1** belongs to an infection-specific secondary metabolite gene cluster (Scheme 1),6 expressed only during appressorium-mediated penetration, and not at any other stage of the *M. oryzae* life cycle.7 The 12.4 kb **ACE1** gene encodes an enzyme consisting of a fungal highly-reducing polyketide synthase (hrPKS)6 fused to a single module of a nonribosomal peptide synthetase (NRPS).8 Similar fungal synthetases have been investigated genetically and biochemically and are known to produce acyl tetracamic acids or pyrrolidones including pretenellin A1,9 preufarin C2 (ref. 10) and preaspyridine A3 (ref. 11 and 12) as well as other potent bioactive compounds including cytochalasin K4 (ref. 13 and 14) and the important cholesterol biosynthesis inhibitor lovastatin5 (ref. 15) (Scheme 1). It appears likely, therefore, that **ACE1** encodes a biosynthetic protein which makes a small molecule consisting of a polyketide fused to an amino acid. Because **ACE1** is under very tight temporal and cell type-specific control in *M. oryzae*, it has not yet been possible to identify or purify the avirulence compound.

Knowledge of the **ACE1** metabolite structure would be highly useful for investigating avirulence signalling and developing novel resistant cultivars. The research of our group and that of others has focused on the heterologous expression of other fungal PKS-NRPS genes in *Aspergillus oryzae* from gene clusters of known function.10,16–19 Here we set out to use heterologous expression of genes from a cryptic pathway to determine its
unknown chemical product, since knowledge of the ACE1 compound will enhance efforts to design new compounds of high potential utility in crop protection.

**Results**

In initial experiments a construct known to express ACE1 in M. oryzae, containing ACE1 fused to egFP at its 3′ terminus (pPACE1-ACE1eGFP-hyg), was used to construct the vector pPamyB-ACE1eGFP-argB (Fig. 1A) in which the ACE1-eGFP gene fusion was located downstream of PamyB.

This plasmid was then used to transform A. oryzae M-2-3. Transformants were selected on minimal medium and 100 colonies were selected and grown further on both minimal medium and minimal medium plus maltose. Four transformants showed weak fluorescence and these were picked together with 10 non-fluorescent transformants and grown in liquid medium (see ESI†). The resultant organic extracts were examined by LCMS but no significant chemical differences were observed between extracts from any of the transformants and the untransformed A. oryzae M-2-3 strain (data not shown).

**Intron processing**

Since A. oryzae is increasingly being used as a heterologous host for studying gene expression, we wanted to determine why our initial attempt at expressing ACE1 had failed. The ACE1 gene contains three introns located between exons corresponding to PKS domains (Fig. 1B). As there is a possibility that A. oryzae may not always splice heterologously expressed genes the same way as the host organism, we explored how the introns of ACE1 are processed by A. oryzae and M. oryzae.

Each ACE1 intron was amplified with ca. 20 bp of flanking 5′ and 3′ exon sequences and cloned as in-frame fusions with egFP downstream of either the native ACE1 promoter (Pace1), the strong constitutive promoter PpgdA from Aspergillus nidulans or the inducible promoter PamyB from A. oryzae. A total of nine plasmids were constructed (Fig. 1C). These constructs were transformed into either A. oryzae or M. oryzae, along with positive and negative controls, selected on the appropriate selection media and observed for fluorescence (Table 1 and Fig. 2). RT-PCR was performed for each intron construct using primers located either side of the introns and the products were sequenced (see ESI† for details).

The results demonstrated that introns 1 and 3 are spliced identically in A. oryzae and M. oryzae whereas incorrect splicing of intron 2 by A. oryzae results in a frameshift and premature stop codon (Fig. S1†).

**Heterologous expression of ACE1**

Based on results from the intron processing experiments, we created two modified expression plasmids for further attempts to produce the ACE1 compound (Fig. 1A). The first consisted of the entire ACE1 gene lacking all introns fused to egFP (pPamyB-ACE1[Δintron1-3]eGFP-argB); the second consisted only of the PKS encoding portion of ACE1 – also fused to egFP, and containing only intron-3 (pAmyB-ACE1ps[Δintron1-2] egFP-argB, see ESI† for construction details). Controls included empty vector and egFP alone (pPgpdA-eGFP-hyg, Fig. 1D). These plasmids were used to transform A. oryzae M-2-3 and selection was achieved on minimal medium supplemented with hygromycin where appropriate. On malt extract agar (MEA) the selection was achieved on minimal medium supplemented with hygromycin where appropriate. On malt extract agar (MEA) the transformants containing the ACE1 constructs produced a bright yellow colour, while the controls were colourless. Twenty colonies were selected for each construct, grown in liquid medium and extracted as described above. All transformants tested clearly produced a new peak compared to the controls (Fig. 3A) in the neutral organic extract, and in lesser amounts, in the acidic and mycelial extracts.

The new compounds appeared to be identical for the two ACE1 expression constructs (RT = 33.2 min; uv max = 214, 272,
361 nm; $m/z = 315$ [M]Na$^+$, 293 [M]H$^+$, 275 [M – H$_2$O]H$^+$. Both compounds were purified and shown to be identical by NMR and HRMS ($m/z$ 291.1238 Da [M – C$_{16}$H$_{20}$O$_5$], consistent with a molecular formula of C$_{16}$H$_{20}$O$_5$).

$^1$H NMR analysis (see ESI†) showed that the sample consisted of a 1 : 1 mixture of diastereomers each of which contained three methyl groups, a CHX, five contiguous olefinic protons, and two sharp doublets ($J = 2.0$ Hz) in the olefinic region. COSY correlations were used to determine that the olefinic protons were part of a distinct spin-system with an olefinic methyl group, connected by a vicinal coupling, visible only as a slight broadening of the terminal olefin doublet in the 1D $^1$H NMR. The COSY also showed that the CHX (which appeared as a complex multiplet) and one of the methyl groups (itself appearing as a pair of doublets) formed another distinct coupling system. An HMBC spectrum determined that the lone methyl group and olefins were all part of the same chain with a formula of C$_{11}$H$_{17}$O$_2$, leaving C$_5$H$_3$O$_3$ unaccounted for. The characteristic $^{13}$C NMR resonance of $d$163.6 ppm revealed that an ester group was present in the structure accounting for a further CO$_2$, and leaving C$_4$H$_3$O unassigned. The remaining two unassigned protons showed HMBC correlations to the ester carbonyl and two other quaternary carbons, the chemical shifts of which ($d$ 162.4 ppm and $d$ 162.6 ppm) were consistent with enolic carbons. Although these protons were coupled, they did not appear to be on adjacent

M. oryzae

amino acid required by the ACE1 NRPS in secondary metabolites detected using LCMS; 12,13-dihydroxy-

selected transformants were grown in liquid medium and turbulence by the C-terminal eGFP fusion we modi-

the expected amino acid component. To rule out NRPS per-

expression system to remove the 3

methyl doublet of

was replaced by a methyl doublet

was a single

label at C-15 and C-16.

Thus 6 consists entirely of a polyketide and does not contain the expected amino acid component. To rule out NRPS perturbation by the C-terminal eGFP fusion we modified the expression system to remove the 3'-eGFP gene to create pPamYB-ACE1[Δintrons1–3]-argB and transformed A. oryzae M-2-3. Selected transformants were grown in liquid medium and secondary metabolites detected using LCMS; 12,13-dihydroxymagnaporthepyrone 6 was the only new compound detected.

To overcome the possibility that A. oryzae lacks the specific amino acid required by the ACE1 NRPS in M. oryzae we constructed plasmids for homologous expression of ACE1 in M. oryzae Guy11 using the P_gpdA constitutive promoter and hygromycin selection. We thus constructed an E. coli shuttle vector based on the pUC18 vector with a Gateway cassette downstream from P_gpdA carrying a hygromycin resistance marker. The ACE1 eGFP construct was transferred into this vector by Gateway LR recombination in vitro to give pPgpDA-ACE1eGFP-hyg which was used to transform M. oryzae Guy11. The plasmid pPgpDA-ACE1eGFP-hyg was used as a control. Hygromycin resistant transformants were selected for each construct and grown on complete medium plates and examined for fluorescence. For pPgpDA-eGFP-hyg, 18/20 transformants were fluorescent while only 5/100 of the pPgpDA-ACE1eGFP-hyg transformants were fluorescent.

The five M. oryzae transformants expressing ACE1eGFP were then grown in complete liquid medium for 7 days then extracted and examined by LCMS as described in the ESI.† All five transformants produced a new compound which was not produced by the controls. This compound had a different retention time to 12,13 dihydroxymagnaporthepyrone 6 produced in A. oryzae (RT = 31.6 min, Fig. 3B) and a different UV spectrum (uvmax = 210 nm, 248 nm, 340 nm) although the low resolution ESI MS spectrum was identical to 6, as was the molecular formula predicted from the HRMS. Thus it appeared that this compound was isomeric to 12,13-dihydroxy-
magnaporthepyrone 6. 1H NMR showed it to consist of a single stereoisomer, but compared to 6 it had only three contiguous olefinic CH resonances, one of which was coupled to a CHO methine which was in turn coupled to another CHO methine. The methyl doublet of 6 was replaced by a methyl doublet coupling to an olefinic CH. These data, supported by 13C and 2D spectra showed this compound to be 10,11-dihydroxymagnaporthepyrone 7.

**Co-expression with the RAP1 trans-ER protein**

Bioinformatic analysis of the sequence of the ACE1 enoyl reductase (ER) domain suggests that it is inactive, similar to the tenellin and lovastatin nonaketide synthase (LNKS) ERs – such domains are designated ER\(^{2}\) to indicate their non-catalytic role. Many fungal hrPKS which contain an ER\(^{2}\) domain recruit a trans-acting ER which has a catalytic and programming role. For example in the cases of pretenellin A 1, preaspyridone 3 and lovastatin 5 biosynthesis trans-acting ERs encoded by tenC,
apdC and lovC respectively interact with the PKS to provide programmed enoyl reduction and have the effect of reinforcing PKS programming including methylation and chain-length fidelity.13 RAP1 also encodes a trans-acting ER (e.g. RAP1 has a 48% similarity to TENC and 58% similarity to LOVC) and thus it may play a similar role in concert with ACE1, possibly controlling fidelity as well as enoyl reduction. We therefore constructed plasmids to coexpress RAP1 with ACE1 in both A. oryzae and M. oryzae.

For A. oryzae we created a plasmid carrying both the ACE1 and RAP1 genes in which ACE1 lacking all introns was expressed under the control of PamyB, and RAP1 was expressed from the strong constitutive alcohol dehydrogenase promoter Pasb from A. oryzae (pPamyB-ACE1 [Δintrons 1–3] - argB - Padh - RAP1, Fig. 1A). A. oryzae M-2-3 protoplasts were transformed with pPamyB-ACE1 [Δintrons 1–3] - argB - Padh - RAP1 and transformants were selected on minimal medium.

Twenty seven of the resulting A. oryzae transformants were selected and transferred to new agar plates. Ten of these transformants, A. oryzae M-2-3 protoplasts were transformed with pPamyB-ACE1 [Δintrons 1–3] - argB - Padh - RAP1 and transformants were selected on minimal medium.

A single A. oryzae transformant was grown at large scale (800 mL) to yield 65.5 mg of crude extract. The new compound was purified by HPLC and analysed by NMR and HRMS (m/z 482.3265 Da [M - H]+, consistent with a molecular formula of C30H43NO4). 1H NMR analysis showed that the compound contained four methyl groups, six olefinic protons and an aromatic group indicative of tyrosine. 13C NMR, COSY, HMBC and HSQC determined the structure as 8 (Fig. 6, ESI†).

**Biological testing**

Purified magnaportheapyrones 6 and 7 were tested for biological activity on susceptible, (Maratelli, Sariceltik CO39) and resistant rice cultivars carrying Pi33 (IR64 and C101LAC). Compounds were deposited onto normal or wounded rice leaves. Both compounds induced localised brown necrosis on all cultivars, irrespective of host genotype (Fig. 7). These results suggest that magnaportheapyrones do not induce a phenotype specifically on rice cultivars carrying Pi33. Addition of these compounds to spore suspensions of an isolate virulent on Pi33 rice cultivars did not induce an AVR reaction, but slightly reduced pathogenicity on both susceptible and resistant cultivars. Compound 8 had no biological activity: no induction of leaf symptoms, no changes of a virulent interaction into AVR, no enhancement nor reduction in pathogenicity. Therefore compounds, 6, 7 and 8 do not appear to be the avirulence signal compound produced by ACE1/M. oryzae Guy11 during appressorium-mediated penetration.

![Fig. 7 Biological testing of 12,13-dihydroxymagnaportheapyrone 6 on both resistant (IR64 and C101LAC) and susceptible (Maratelli) rice cultivars. Testing of 7 gave similar results. 8 Had no effect.](Image)
Discussion

Initial attempts to express ACE1 in A. oryzae produced no observable new metabolites. This was surprising as all of our previous efforts to express foreign fungal genes in this organism had been successful.

Further investigation using RT-PCR and subsequent sequence analysis clearly showed that ACE1 intron-2 is not spliced correctly in A. oryzae, resulting in an mRNA with a frame-shift and premature stop codon. Intron-2 is located centrally in the PKS portion of ACE1, upstream of the sequence encoding the key acyl carrier protein (ACP) domain. Any truncated ACE1 protein resulting from the translation of this incorrectly spliced mRNA would not be capable of producing a polyketide product.

Removal of the ACE1 introns resulted in transcripts which were translated correctly in A. oryzae. Indeed more than 75% of transformants produced full-length ACE1-eGFP protein fusions as evidenced by strong fluorescence of transformed hyphae, and the production of novel metabolites. Expression of both full-length and NRPS-deleted ACE1 intronless constructs resulted in the production of the same compound, 12,13-dihydroxymagnaporthepyrone 6 which is exclusively of polyketide origin as shown by isotopic labelling. Expression of the same clones in M. oryzae resulted in the production of the closely related 10,11-dihydroxymagnaporthepyrone 7. These results are consistent with the observation that the ACE1 ER domain is predicted to be inactive. Coexpression of ACE1 with RAP1, which encodes a trans-acting ER, changed the biosynthetic pathway. In the heterologous host A. oryzae, where we constructed a single vector to carry both genes, the amide 8 was produced and compounds derived from 9 were no longer observed.

Amide 8 is closely related to pyrone 9 and its biosynthesis can be rationalised by the intervention of the RAP1 ER at the pentaketide stage of biosynthesis (Scheme 2). Pentaketide intermediate 12 is recognised by the ACE1 KS domain and extended to 13, but in the absence of prior enoyl reduction the next required CMeT step is prevented. Continued chain extension by an unselective KS then gives the tricarbonyl 14 which can spontaneously offload itself from the synthase as the pyrone 9. Alternatively, in the presence of the RAP1 ER, pentaketide 12 is reduced giving a substrate which can be extended by the KS and then correctly methylated to give 15 before following three

Scheme 2  Deduced biosynthesis of ACE1 products in the presence and absence of RAP1. X = ACE1 ACP domain.
more extension and processing cycles to give the fully extended nonaketide 16. Thus the ACE1 CMeT domain appears to display an additional level of substrate selectivity in blocking correct chain processing in the absence of 10,11 reduction. Crucially, however, the KS is unselective and continues to extend the chain to the tricarbonyl 14 which can be off-loaded as the pyrone 9. Thus the lack of selectivity by the KS effectively removes incorrectly processed chains from the PKS, preventing its blockage.

In many other investigated PKS-NRPS systems the NRPS then attaches the amino acid to the fully extended polyketide and either reductively cleaves it, or performs a non-reductive Dieckmann cyclisation reaction to release an acyl tetramic acid. In this case it appears that tyrosine is used as the amino acid and attached to the polyketide in the same way as observed in the cases of pretenellin A and preaspyridone. After amide formation, however, the fully elaborated product is probably reductively released. This could be via 2 electron reduction to form an aldehyde (as in the classic case of fungal lysine reductively released. This could be called PKS-NRPS). Consistent with this hypothesis is the observation that the ACE1 terminal-domain has an intact conserved NADPH binding motif (GXVXXG) and the catalytic triad Ser-Tyr-Lys more closely resembles ‘reducing’ R-domains than DKC cyclising domains (see ES1).

Qiao et al. predicted a reductive release for ccsA, the PKS-NRPS gene involved in cytochalasin K biosynthesis, most likely via ketoacytochalasin 18. Although 17 is unlikely to be a direct precursor of 4, it is probably a shunt metabolite from the corresponding aldehyde. Vederas, Tang and coworkers have also recently elucidated that ccsB from the cytochalasin K biosynthetic pathway is an FAD-dependent oxygenase which catalyses (among other reactions) the creation of the distinctive carbonate moiety of 4. The structural similarities between the ccsA/C product 17 and the ACE1/RAPI product 8 strongly suggest that 8 is also a shunt metabolite of a cytochalasan-like biosynthetic pathway. This is supported by the observation that 8 does not show the expected biological activity as an avirulence signalling compound.

To our knowledge, only two other gene clusters have been correlated with cytochalasan biosynthesis in fungi. These are the gene clusters for chaetoglobosin A biosynthesis in Penicillium expansum and Chaetomium globosum. Chaetoglobosin A is biosynthesised from tryptophan and a nonaketide likely to be almost identical to that of amide 8, except for the unsaturation between carbons 4 and 5. However, several chaetoglobosins are also known which are fully saturated at this position (e.g. chaetoglobosin C). indicating that amide 8 could include the correct polyketide precursor. Analysis of the tailoring genes in the ACE1 cluster show that they have more similarity to the chaetoglobosin biosynthetic genes than those in the ccs cytochalasin gene cluster (Table S2†).

The Oikawa compound 17 differs from 8 in being an octaketide rather than a nonaketide and being evidently constructed from phenylalanine rather than tyrosine (Scheme 3). A further difference is that 8 is unsaturated between carbons 8 and 9 of the polyketide, whereas 17 is fully saturated at the corresponding position. Genetic experiments have already shown that ccsA and ccsC are involved in cytochalasin K biosynthesis, most likely via ketoacytochalasin 18. Although 17 is unlikely to be a direct precursor of 4, it is probably a shunt metabolite from the corresponding aldehyde. Vederas, Tang and coworkers have also recently elucidated that ccsB from the cytochalasin K biosynthetic pathway is an FAD-dependent oxygenase which catalyses (among other reactions) the creation of the distinctive carbonate moiety of 4.
The nonaketide nature of the amide 8 and the fact that tyrosine is incorporated, distinguishes the RAP1/ACE1 product from the ccsA/ccsC compound and mean that the likely ultimate product of the ACE1 pathway will be a member of the tyrosine-derived cytochalasans, an example of which is phomopsichalasin (also known as diaporthichalasin) 21. In addition, the differences between the ACE1 and ccs gene clusters, such as the lack of a ccsB homolog, plus additional oxidoreductases similar to those found in the chaetoglobosin A 19 gene cluster, indicate that the tailoring of the polyketide backbone is likely to be more similar to 19, which could arise from a polyketide identical or very similar to that of 8.

Thus we have shown that heterologous expression is an effective tool to probe cryptic gene clusters in fungi, which enables important metabolic relationships to be unravelled. It is now clear that avirulence signalling between the rice blast fungus Magnaporthe oryzae and rice is mediated by a natural product bearing structural similarities to the cytochalasans. Current and future work in our group is focused on exploring the enzymatic activities of the proteins encoded by other genes from the ACE1 biosynthetic cluster to identify the bioactive compound responsible for avirulence signalling.
