## **Abstract**

During the Cretaceous (145.0 to 66.0 Myr) elevated atmospheric CO<sub>2</sub> levels resulted in Oceanic Anoxic Event (OAE) causing widely spread “black shales” and an abrupt increase in temperature. The climate of this period was disturbed by a few short-lived but prominent cooling events, interrupting the prevailing greenhouse conditions. An outstanding high global sea level, the submergence of several continental plates, and the evolution of large shelf areas favoured the development of isolated shallow marine carbonate platforms. The latter were exceptionally widespread, particularly in and around the Tethyan realm. There they built large and complex sedimentary systems, which have been repeatedly devastated by fast-changing environmental conditions. Rudists, an order of gregarious, sediment dwelling, heterodont, bizarrely shaped, sessile bivalves were the main carbonate producers.

Shallow marine carbonate platforms are a valuable archive for the reconstruction of deep-time environmental and climatic conditions due to their quick reaction to environmental changes. Their often-low resolution of biostratigraphic schemes makes a precise chronostratigraphic classification difficult, resulting in a fragmentary record.

In order to reconstruct palaeoenvironmental conditions, a precise chronostratigraphic framework was established. Two sections, the platform marginal Monte La Costa and the inner lagoonal Santa Lucia sections, located on the Apennine carbonate platform, were analysed in great detail, using an integrated bio- (calcareous algae and benthic foraminifera) and chemostratigraphic (C-, O- and Sr-isotope analysis) approach. Furthermore, both sections were correlated with well-dated pelagic reference curves and with each other. Several exposure surfaces and their related temporal gaps were detected at both sections and dated precisely.

A microbial episode appearing on the Apennine Carbonate Platform was detected in both sections. Its coeval onset was dated, using the aforementioned framework, to the OAE1b, between the Jacob and Kilian black-shale level especially. The main phase of bacinelloid growth can be linked to the subsequent temperature rise after the Late Aptian cold snap as well as an increase in sea level.

In order to use low-Mg calcite radiolitic shells as a palaeoenvironmental archive, a first approach of high-resolution sampling, using isotopic and elemental data, was applied. Shells were selected using literature based thresholds. Sclerochronological profiles were created and various shell structures (compact and porous) described. The results of selected shells are promising: The smooth, sine functional  $\delta^{18}\text{O}$  pattern in the compact left valve may be used for palaeotemperature and palaeosalinity reconstructions. In the right valves two microstructure types were classified: Shells, where compact and non-compact parts alternating, might be used for palaeoenvironmental reconstructions, while those that contain a celluloprismatic structure, can be used only for habitat reconstructions, as the isotopic and elemental dataset shows the impact of diagenetic alteration.

**Keywords: Shallow marine carbonate platform; Cretaceous; Rudist**

## Zusammenfassung

Gase aus vulkanischen und/oder methanogenen Quellen erhöhten während der Kreidezeit (145,0 bis 66,0 Ma) den atmosphärischen CO<sub>2</sub>-Gehalt, was zu Ozeanischen Anoxischen Events (OAE) und den damit weit verbreiteten "Schwarzschiefern" führte. Das Klima dieser Zeit wurde durch einige kurzlebige aber markante Abkühlungen geprägt, welche die ansonsten vorherrschenden Treibhausbedingungen unterbrachen. Ein außergewöhnlich hoher globaler Meeresspiegel, die Überflutung mehrerer Kontinentalplatten und die Entwicklung großer Schelfgebiete begünstigten die Entwicklung isolierter, flach-mariner Karbonatplattformen. Letztere waren, insbesondere in und um den Bereich der Tethys, weit verbreitet. Dort wurden große und komplexe Sedimentsysteme ausgebildet, die durch schnell ändernde Umweltbedingungen immer wieder zerstört wurden. Rudisten, eine Ordnung von sedimentbewachsenden, heterodontalen, bizarr geformten, festsitzenden Muscheln, waren die Hauptkarbonatproduzenten.

Flach marine Karbonatplattformen sind wegen ihrer schnellen Reaktion auf Umweltveränderungen ein wertvolles Archiv für die Rekonstruktion von Umwelt- und Klimabedingungen. Dennoch sind sie aufgrund der geringen biostratigraphischen Auflösung und der damit verbundenen erschwerten chronostratigraphischen Klassifizierung oft schwer zu entschlüsseln. Zusätzlich wird eine zeitliche Einordnung oft durch Lücken erschwert, die durch Expositionsoberflächen verursacht werden, sodass die Sedimentation oft als fragmentarisch erscheint.

Um die paläoökologischen Bedingungen zu rekonstruieren, wurde ein präziser chronostratigraphischer Rahmen geschaffen. Zwei Abschnitte auf der apenninischen Karbonatplattform, der am Plattformrand gelegene Monte La Costa und der im inneren der Lagune gelegene Santa-Lucia Aufschluss, wurden mit einem integrierten bio- (Kalkalgen und benthische Foraminiferen) und chemostratigraphischen (C-, O- und Sr-Isotopenanalyse) Ansatz analysiert. Darüber hinaus wurden beide Abschnitte mit gut datierten pelagischen Referenzkurven und untereinander korreliert. Mehrere Expositionsflächen und die damit verbundenen Zeitverluste wurden bei beiden Aufschlüssen erfasst und präzise datiert.

Eine mikrobielle Blüte, die auf der Apenninkarbonatplattform auftritt, wurde in beiden Abschnitten nachgewiesen. Ihr zeitgleicher Beginn wurde unter Verwendung des oben genannten Rahmens auf das OAE1b datiert, auf das Intervall zwischen dem Jacob- und Kilian-Schwarzschiefererevent. Die Hauptphase des bacinelloiden Wachstums ist mit dem Temperaturanstieg korreliert, der auf den Late Aptian ‚Cold Snap‘ folgt, sowie mit einem Meeresspiegelanstieg.

Um Radiolitidenschalen aus Tief-Mg Calcit als Paläoumweltarchiv zu nutzen, wurde ein erster Versuch unternommen, Isotopen- und Elementdaten hochauflösend zu messen. Die Auswahl der Schalen erfolgte anhand von literaturbasierten Grenzwerten. Es wurden sklerochronologische Profile erstellt und verschiedene Schalenstrukturen (kompakt und porös) beschrieben. Die Ergebnisse

ausgewählter Schalen sind vielversprechend: Das zyklische, sinusförmige  $\delta^{18}\text{O}$ -Muster in der kompakten, linken Klappe kann für Paläotemperatur- und Paläosalinitätsrekonstruktionen verwendet werden. In den rechten Klappen wurden zwei Mikrostrukturtypen klassifiziert: Schalen, bei denen kompakte und nicht-kompakte Teile abwechselnd zu finden sind, können für paläoökologische Rekonstruktionen verwendet werden, während solche, die eine celluloprismatische Struktur enthalten, nur für die Rekonstruktion des Lebensraums verwendet werden können, da der isotopische - und elementare Datensatz die Auswirkungen diagenetischer Veränderungen zeigt.

**Stichworte: Flach marine Karbonatplattformen; Kreide; Rudisten**

## **1. Introduction**

### **1.1 The Cretaceous: A Period of Extremes**

The Cretaceous, ranging from 145.9 to 66.0 Myr is subdivided into 12 stages based on chemo-, magneto-, cyclo- and biostratigraphy (Gradstein et al., 2012). The latter is based on ammonite ranges (Birkelund et al., 1984; Kennedy, 1984) supported by calcareous nannofossil data (Gradstein et al., 2012). The Cretaceous period includes the zenith of the dinosaurs, the rise of land flowering plants (angiosperms), the first occurrence of birds and the massive bloom of coccolithophores forming large chalk deposits, which gave the Cretaceous its name. It was terminated by a major mass-extinction at the K/Paleogene boundary (Gradstein et al., 2012; Skelton et al., 2003).

During the Cretaceous several extraordinary events occurred: The breakup of the supercontinent Pangaea, into Laurasia in the north and Gondwana in the south, has already advanced creating equatorial new sea passages, namely the east-west orientated Tethys at low latitudes and the narrow Central Atlantic (Skelton et al., 2003).

The global sea level rose to its maximum during the Late Cretaceous (dark blue curves in Fig. 1.1). This was triggered by the growth of new mid-ocean ridge systems and by an increased production of oceanic crust that caused the displacement of water from oceanic basins (Skelton et al., 2003). The increasing sea level caused the submergence of several continental plates while other continents were surrounded by large shelf areas (Hennhöfer, 2013). Thus, conditions were in favour of the development of isolated shallow marine carbonate platforms, shallow seas, and barrier reefs (Frakes et al., 1992; Skelton et al., 2003).

The Cretaceous climate is classified as a greenhouse world interrupted by short-lived but prominent cooling events (cold snaps; green squares in Fig. 1.1) during the Berriasian-Valanginian, earliest Late Valanginian, earliest Aptian and Late Aptian (Weissert, 1991; Hochuli et al., 1999; Miller et al., 1999; Pucéat et al., 2003; Skelton et al., 2003; Steuber et al., 2005; Bornemann et al., 2008; Mutterlose et al., 2009). Amongst other factors, cooling is evidenced by dropstones and glendonites found at higher latitudes in the marine realm (Mutterlose et al., 2009). Using foraminifera and belemnite oxygen isotope ratios and TEX<sub>86</sub> data, a temperature maximum of 37 °C was reconstructed (light blue curve in Fig. 1.1; Huber et al., 1995; Bornemann et al., 2008; Mutterlose et al., 2009; Skelton et al., 2003; Huber et al., 2011; Bodin et al., 2015; Friedrich et al., 2012; McAnena et al., 2013). Polar forests reaching up to 82°N support this hypothesis. These polar forests were habitats for plants (conifer needles), shells, fish, crocodiles and turtles as well as herbivore and carnivore dinosaurs (Francis and Frakes, 1993; Frakes et al., 1992; Skelton et al., 2003; Huber, 1998). The low equator to pole temperature gradient was responsible for a weak atmospheric and oceanic circulation (Frakes et al., 1992).

**Fig. 1.1:** Compilation of major environmental changes during the Cretaceous including sea level changes in dark blue (Haq et al., 2014); SST (sea surface temperature) changes using TEX<sub>86</sub> (light blue) for low palaeolatitude after O'Brien et al. (2017) and rudist ranges (purple) after Steuber (2005), possible cold snaps (green) after Hu et al. (2012), the reconstructed range of palaeo-CO<sub>2</sub> (yellow) after Wang et al. (2014) with the minimum values of Berner (1994) and maximum values of Ekart et al. (1999); LIPs (large igneous provinces: A-C: Caribbean Columbian Province; Ant.: Antarctic Lamprophyre; D: Deccan Traps; HA: High Arctic Large Igneous Province; HP: Hikurangi Plateau; Ind.: Indian Lamprophyre; M: Madagascar; MP: Manihiki Plateau; OJP 1: Ontong Java Plateau Event 1; OJP 2: Ontong Java Plateau Event 2; P-E: Paraná–Etendeka traps; Raj.: Rajmahal Traps; SKP: Southern Kerguelen Plateau; W: Whitsunday) compiled after Bryan et al. (2012), Bottini et al. (2015) and Gradstein et al. (2012), OAEs (oceanic anoxic events) from Locklair et al. (2011) and Wagreich (2012), δ<sup>13</sup>C values in black in Gradstein et al. (2012) and platform drowning events (pink) after Skelton et al. (2003). All data are adapted to the GTS 2012 (Gradstein et al., 2012).

In addition, it is assumed that the high sea levels were caused by the temporary absence of polar ice caps (Skelton et al., 2003). Transgression as well as temperature maxima were reached during the Turonian (Skelton et al., 2003; Haq et al., 1987; Sahagian et al., 1996; Kominz et al., 2008) with a sea level 200 m higher than today (Haq et al., 1987; Skelton et al., 2003) and thus the highest level recorded throughout the Phanerozoic (Miller et al., 2005). The transgression was caused by high sea floor

spreading rates (Skelton et al., 2003) triggered by an increased productivity of oceanic crust (Larson, 1991). This enhanced oceanic crust production resulted in an elevated atmospheric CO<sub>2</sub> level (Jones and Jenkyns, 2001) that was at least three times higher than today (Bice et al., 2006; Caldeira and Rampino, 1991) (yellow curve in Fig. 1.1). Additionally, the atmosphere was affected by volcanic gases emitted from large igneous provinces (LIPs) or methanogenic sources (Jenkyns, 2010) (red asterisks in Fig. 1.1). This rapid emission of vast amounts of CO<sub>2</sub> resulted in an abrupt increase in temperature (Jenkyns, 2010) that most likely caused the formation of widely spread “black shales”: organic-rich lithologies in which a large quantity of organic carbon was buried (Arthur et al., 1987; Arthur et al., 1990). These globally important organic-carbon burials, termed Oceanic Anoxic Event (OAE) (Arthur et al., 1990), are related to global short-lived major perturbations in the carbon cycle. OAEs are marked as positive anomalies in several carbon isotope records (Scholle and Arthur, 1980) of pelagic deposits and occasionally in shallow marine carbonate platform limestones (black curve in Fig. 1.1). An advantage of pelagic deposits is their continuous record which allows global and local correlations. However, shallow marine carbonate platforms react fast to environmental changes but contain often a fragmentary record. Therefore, they pose a high potential as well as one of the greatest challenges to the research of palaeoenvironmental reconstruction.

## 1.2 Carbonate Platforms: A Shallow-Water Ecosystem

The distribution of landmasses combined with high sea levels provided excellent conditions for an accumulation of shallow marine limestones in low latitudes (Fig. 1.2). These carbonate platforms were exceptionally widespread, particularly in and around the Tethyan realm, where they built large and complex sedimentary systems with regional variations (Skelton et al., 2003).

**Fig. 1.2:** Palaeogeographic reconstruction of shallow marine carbonate platforms (light blue) in low latitudes during the Late Cretaceous (98 Ma) modified after Skelton et al. (2003).

Cretaceous carbonate platforms were composed of algae with calcareous skeletons, gastropods, scleractinian corals, benthic foraminifera and a distinct shelly benthos, mainly rudists. The latter were the main carbonate producers building extensive meadows spread across low relief sediment (Skelton et al., 2003).

Due to sea level oscillations and tectonic activity, two settings alternated in the Cretaceous: The exceptional rapid growth and expansion of platforms, which was interrupted by short but global episodes of their demise (Fig. 1.3). Particularly outstanding declines can be recognized during the Mid Valanginian, the Early and Mid Aptian, the Cenomanian/Turonian and finally in the Late Maastrichtian. Those drownings or collapses of the carbonate producing systems (Masse and Philip, 1986; Ross and Skelton, 1993) were caused by processes like a sea level rise/drop or the infiltration by microencrusting species, e.g. *Lithocodium aggregatum* Elliott (1956) and *Bacinella irregularis* Radoičić (1959) that replaced the previously dominant shelly biota (Immenhauser et al., 2005).

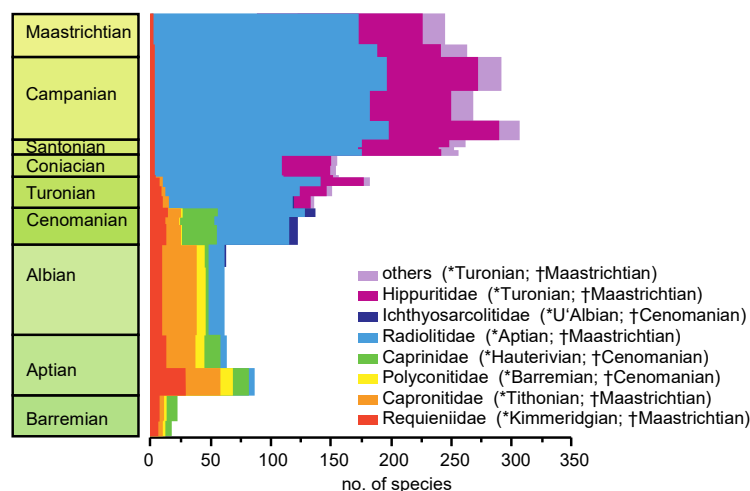

**Fig. 1.3:** Major crises that are often correlated to OAEs, interrupting the carbonate platform evolution during the Cretaceous in the Tethyan/Atlantic oceanic realm modified after Skelton et al. (2003). Aptian to Cenomanian period are highlighted to show studys' focus.

Although it is often difficult to decipher them, shallow-water carbonate platform sections are a valuable archive for the reconstruction of deep-time environmental and climatic conditions due to their

quick response to environmental changes. But the low resolution of biostratigraphic schemes often hampers their precise chronostratigraphic classification and the fragmentary record. This is caused by diagenetic alteration and exposure surfaces. However, it is possible to date such sections using integrated bio- and chemostratigraphy. As a start, biostratigraphy is used for an initial age assessment. Then, carbon isotopes values are measured and utilized to correlate shallow marine sections with well-dated pelagic sections. In addition, carbon and oxygen isotope analyses are valuable tools to identify exposure surfaces (negative values) and to exclude samples that were altered by meteoric diagenesis. The latter is often indicated by a correlation between  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  values or increasingly negative  $\delta^{13}\text{C}$  values with constant  $\delta^{18}\text{O}$  values (Gradstein et al., 2012). This process is then followed by strontium isotope stratigraphy (SIS). In order to exclude diagenetic altered samples, suitable low-Mg calcite shells with high Sr and Mg but low Mn and Fe concentration needs to be identified by Inductively Coupled Plasma-Optical Emission Spectrometry (ICP-OES) (Steuber, 1999). This elemental analysis allows for the identification of the best-preserved and best-suited material.

### 1.3 Rudists: Main Producers of Shallow Marine Carbonate Platforms during the Cretaceous

Rudists (superfamily Hippuritoidea), an order of gregarious, sediment dwelling, heterodont, bizarrely shaped sessile bivalves, evolved during the Late Jurassic (Skelton and Smith, 2000) and were extinct at the K/Paleogene boundary (Skelton et al., 2003; Skelton, 1978). During the Early Aptian the abundance and spreading of rudist species increases (Fig. 1.4; Steuber and Löser, 2000). Colonizing an entire platform (from low energy inner platform settings to high energy shelf marginal settings), carbonate ramps and seamounts (Rauch, 2005), they dominated the carbonate platforms in the Tethyan ocean and were the main carbonate producers with a carbonate production rate of 2.2 to 35.7 kg  $\text{CaCO}_3 \text{ m}^{-2}\text{year}^{-1}$  (Skelton et al., 2003).

**Fig. 1.4:** Number of species recorded in the Mediterranean and Middle East region from the Barremian to the Maastrichtian including the global ranges of the families modified after Steuber and Löser (2000).

Although they are often described as reef biota, they did not built reefs but “meadows” (Skelton et al., 2003). While growing in bouquets (few specimens attached to each other), clusters (dozens together) or thickets (> 100 rudists) (Philip, 1972; Hennhöfer, 2013). Rudists developed several different growth forms and morphotypes in order to adapt to and occupy various habitats (Fig. 1.5):

1. Recumbents (Fig. 1.5 A) lay prone but unattached on mobile lime sand or shelly rubble substrate in a current-swept environment, where no significant sediment accumulation occurred during their lifespan (Ross and Skelton, 1993). Due to a platform drowning event in the Late Cenomanian (Fig. 1.3), all recumbents that thrived in the outermost platform environment went extinct.
2. Clingers (Fig. 1.5 B) consisted of an attached valve with a large basal surface (horizontal growth) and an “unattached” one (growth inclination of 45°). They grew on stable substrate and tolerated occasional sediment influx and currents.
3. Elevators (Fig. 1.5 C) formed an elongated attached valve that was stabilized by surrounding sediment or by an attachment to the neighbouring rudist (clustering). Due to their need of surrounding sediment, they implanted in an accumulating sediment environment (Skelton and Gili, 1991, Skelton et al., 2003).

All rudist species formed their shell following the same structural design: with two inner aragonitic layers and an outer low-Mg calcite layer. Due to the chemical composition, the outer layer is very stable against diagenetic alteration and hence a valuable archive for recording environmental conditions that prevailed while the shell was secreted. Since rudists are building growth increments, they are considered suitable for sclerochronological analysis. In past studies, they have therefore been used for dating (SIS), the reconstruction of seasonal variations in ocean chemistry (Mg/Ca) and climate reconstruction, which utilize the periodic oscillations of oxygen ( $\delta^{18}\text{O}$ ) and carbon ( $\delta^{13}\text{C}$ ) isotope values in the shell carbonate (Steuber, 2000; Steuber, 2003; Steuber, 1999; Steuber, 1996; Immenhauser et al., 2005; Rauch, 2005).

**Fig. 1.5:** Various morphologies of rudist shells (left half of the figure; Schumann and Steuber, 1997) and their three morphotypes after Skelton and Gili (1991). Right half of the figure: A. Recumbent; B: clinger, C: elevator. A and B show above in plain view (with contact area and basal support) and profile below.

## 1.4 The Apennine Carbonate Platform: A Natural Laboratory

The Apennine Carbonate Platform (ACP) is one of only a few isolated carbonate platforms at the southwest margin of the Tethys (around 15°N; Fig. 1.6 A) that recorded a nearly continuous shallow-water carbonate sedimentation (Skelton et al., 2003; D'Argenio et al., 1973; Frijia et al., 2015) and shows an extremely diverse and abundant rudist assemblage (Frijia et al., 2015).

The ACP contains shallow tropical water carbonate successions and is interpreted as a part of a more or less articulated system of carbonate platforms (including the following units: Capri-Bulgheria, Alburno-Cervati and Monti della Maddalena; Simbruini-Matese; Western Marsica-Meta) (Patacca and Scandone 2007). They are separated by deep water basins and deep water tongues linking the Umbria domain and the Lagonegro-Molise Basin (D'Argenio, 1973; Patacca and Scandone, 2007) (Fig. 1.6 B). The ACP was part of a palaeo-tectonic domain called Adria or Apulia. For further specification of domain name, please refer to Schettino and Turco (2011). It is alternatively interpreted as the promontory of the African continent or as an independent continental block separated from Africa by an oceanic corridor (Decourt et al., 1986; Bosellini, 2002; Schettino and Turco, 2011; Frijia et al., 2015).

During the Mid Triassic, continental rifting created two carbonate platforms: The Apennine and the Apulian platforms, which were separated by the Lagonegro basin (Di Lucia et al., 2012). Shallow-water carbonate sedimentation of the ACP started in the Late Triassic (Cosentino et al., 2010) and stopped at the end of the Cretaceous, when the platform emerged. The sedimentation process continued locally during the Paleogene and the Early Miocene but was finally terminated in the Middle Miocene, when the platform drowned below the photic zone (Frijia et al., 2015) and siliciclastic deep water deposits accumulated (Sgrosso, 1998; Patacca and Scandone, 2007). However, several subaerial exposure surfaces are recorded, containing gaps of various durations. These emersion phases are shown for example by the occurrence of discontinuous lenses of bauxite (Carannante et al., 1988; Ruberti et al., 2013) or brecciated intervals. They were possibly caused by starvation in carbonate production, sea level changes and/or through tectonic uplift (Selli, 1957; 1962).

The ACP contains a 4-5 km-thick sequence of limestones, of which 1-1.2 km were deposited during the Cretaceous (Sartoni and Crescenti, 1962; D'Argenio and Alvarez, 1980; Frijia et al., 2005; Di Lucia et al., 2012). The depositional system of the platform changed over time: from a flat-topped Bahamian-type carbonate platform dominated by chloralgal and chlorozoan associations (D'Argenio et al., 1975) to a ramp-like open shelf setting, dominated by a foramol-type assemblage (Carannante et al., 1997). Due to the continuous sedimentation processes, various bio events (e.g. microbial episodes; *A. reicheli*-Level; *S. dinarica* acme; several *Orbitolina* levels) were recorded and can be used as platform-wide correlation levels.

The outcrops studied in this thesis are located in the southern Apennines in Italy (Fig. 1.6 C) and are located along a SE-NW proximal-to-distal transect across the ACP. The 597 m-thick Santa Lucia

(SL) section, which belongs to the Lazio-Abruzzi carbonate platform, is located along the road cut which connects Villa Santa Lucia and Terelle (41°31'00.6"N 13°46'40.0"E to 41°31'02.0"N 13°47'02.8"E). This succession represents an open lagoon setting, dominated by mudstones alternating with grainstones. Special feature of this outcrop is the bauxitic layer (bx1). The 470 m-thick Monte La Costa (MLC) section, which is part of the Simbruini-Matese unit, is a small mountain range in the Matese Mountains (41°28'12.4"N 14°29'50.0"E) and is interpreted as a platform marginal setting. Grainstones are the dominant facies, alternating with pack- and framestones. In both sections, a bacinelloid-bearing interval of ~ 150 m was recognized.

**Fig. 1.6:** (A) Palaeogeographic map of the Upper Cretaceous with the Apennine Carbonate Platform (red square) in the Tethyan realm. (B) Detailed view of the Apennine carbonate platform (red outline) with surrounded carbonate platforms. ## 1.5 Aims and Objectives

The focus of this thesis is to date and reconstruct major events of the shallow marine Apennine Carbonate Platform (ACP) as well as the reconstruction of mid-Cretaceous palaeoenvironmental parameters using the ACPs' main carbonate producers. Due to a fast reaction to environmental changes, these platforms are valuable archives for the reconstruction of deep-time environmental and climatic conditions (e.g. Di Lucia et al., 2012). Therefore, the ACP was analysed in-depth using various methods to decipher the depositional setting.

Although the ACP is determined as having a more or less continuous sedimentation (Skelton et al., 2003; Frijia et al., 2015), several exposure surfaces (e.g. bauxite, breccias) and related temporal gaps have been reported in several studies. Until now these platforms have solely been dated by means of biostratigraphy, with the result that the chronostratigraphic age of platform successions and/or their possible fragmentary record were solely defined through biozones (e.g. Chiocchini et al., 1989; Mondillo et al., 2011; D'Argenio and Mindszenty, 1995; D'Argenio et al., 2011). Traditionally, biostratigraphy based on benthic foraminifera and calcareous algae was primarily used (e.g. De Castro, 1991; Carannante et al., 2000; Mancinelli and Chiocchini, 2006; Chiocchini et al., 2008), although this approach was limited by the low resolution of shallow-water biozones. However, in recent years more precise chronostratigraphic frameworks have been established using integrated bio- and chemostratigraphy (e.g. Frijia et al., 2015; Parente et al., 2007; Frijia and Parente, 2008).

In order to allow environmental reconstructions of the ACP, a precise chronostratigraphic framework, containing the duration of possible hiatuses, has to be established. To achieve this, the degree of fragmentation needs to be determined as a prerequisite for the framework. Therefore, the first question of this thesis is:

### **(1) To what extent can a continuous sedimentation of the ACP be confirmed?**

Biostratigraphy (foraminifera and algae) was combined with high-resolution carbon isotope stratigraphy and (rudist and chondrodont shell) strontium isotope stratigraphy at the Monte La Costa (MLC) and the Santa Lucia (SL) sections. Both sections were chosen due to their position on the ACP, an open lagoon and a platform marginal setting, in order to create a SE-NW proximal-to-distal transect across the ACP. Through this approach, the sedimentation processes and its continuity can be reconstructed and a very precise chronostratigraphic framework can be established.

During fieldwork, a mass-occurrence of microencrusting organisms was noted in both analysed sections. Their appearance was reported in numerous publications (e.g. Raspini, 2012; Graziano and Raspini, 2015; Mancinelli and Chiocchini, 2006). However, the description of their occurrence differ greatly. Ruberti et al. (2013) describe large *Bacinella/Lithocodium* oncoids and lumps in rock forming abundance from the Upper Aptian portion of the Serra Sbragavitelli section (13 km SW of the MLC

section), assuming that these intercalated oncoid-rich beds are caused by storm events. Di Lucia et al. (2012) mention *Lithocodium-Bacinella* nodules in five sections across the ACP (Mt. Croce, Mt. Raggeto, Mt. Tobenna, Mt. Motola, and Mt. Coccovello). Both the interval thickness and stratigraphic distribution vary (Lower Aptian to Upper Aptian).

To reconstruct the environmental parameters during the appearance of microbial encrusters the newly established timeframe was used. The following question guided the inquiry:

**(2) When was the onset of the microbial episode in each analysed section and what environmental conditions can be reconstructed for this period?**

Based on the scheme of Rameil et al. (2010), morphotypes of the bacinelloidics were defined. Furthermore, the appearance of bacinelloid containing intervals, recorded in the MLC and the SL sections, was tied to the GTS 2012 (Gradstein et al., 2012) and the spatial and temporal expansion of the microencrusters in both sections was compared. Palaeotemperature was determined using  $\text{Tex}_{86}$ . Sea level reconstruction is based on the biostratigraphic data, SIS and cyclostratigraphy (Maurer et al., 2013).

Both analysed sections contained rudist shells, with the MLC showing a high degree of accumulation. Bivalve shells in general are used for palaeoenvironmental reconstructions like temperature or salinity (e.g. Butler et al., 2013; Wanamaker et al., 2011; Schöne et al., 2005). During the Cretaceous, rudist bivalves were generally abundant and are therefore a valid opportunity to reconstruct environmental conditions of that time (e.g. Steuber, 1999; Steuber et al., 2005). They can furthermore be used for strontium isotope stratigraphy, in order to determine their precise chronostratigraphic age (Huck and Heimhofer, 2015). This is due to their low-Mg calcite shell, which is resistant against diagenetic alteration and records palaeoenvironmental conditions (e.g. Steuber, 1999; Regidor-Higuera et al., 2007). Nevertheless, certain rudist genera are preferred for palaeoenvironmental reconstructions due to their compact shell structure.

Interestingly, radiolitids (a family of the order rudists) are mostly excluded from geochemical analyses because of their porous, often cement-filled outer shell layer. Nevertheless, since radiolitids are the primary genus found in the MLC, their abundance poses a significant potential for comprehensive environmental reconstruction. To gain further insights into the usability of radiolitids for environmental reconstructions, the following question arose:

**(3) To what extent are radiolitids a viable basis for environmental reconstruction, especially temperature, salinity and habitat?**

In order to test if it is possible to decipher palaeoenvironmental signals, selected shells are sampled for isotopic record, elemental composition and sclerochronological properties.

## 1.6 Synopsis

The work detailed in this thesis lays a focus on the Apennine shallow marine carbonate platform (ACP) located in Italy, represented by the Monte Cairo Massif (Santa Lucia section; SL) and the Matese Mountains (Monte La Costa section; MLC). It is divided into six chapters, with chapter two stating used methods, chapters three to five addressing the questions stated above (see 1.6) and chapter six giving a conclusive summary of the collected results.

The **second chapter** outlines briefly the sampling and applied methods. Field work and thin section microscopy, isotope-ratio mass spectrometry (Gasbench), Trace Element Analysis and Strontium Isotope Analysis (SIS),  $\mu$ X-ray Fluorescence and Cathodoluminescence (CL) are described.

The **third chapter** addresses question (1), see p. 9. It is comprised of the lithological description and chemostratigraphic analysis of the MLC and SL sections. Both sections were sampled, logged and are described in detail. Using integrated bio- and chemostratigraphy the sections were dated from Barremian to Cenomanian (SL) and from Aptian to Albian (MLC) and a high-resolution framework was established. It was used to determine a fragmentary record of the ACP, including the identification of several exposure surfaces and their resulting variable time losses. Furthermore, sections of the ACP dated previously by biostratigraphy can be inserted in the new chronostratigraphic framework to improve their temporal classification.

Question 2, see p. 10, is the focus of **chapter four**. As both sections are dated using integrated bio- and chemostratigraphy, it appears that the onset of the pervasive bacinelloid microencrusters was coeval in the MLC and SL successions. Its begin is stratigraphically positioned between the Jacob and Kilian black-shale levels of the Late Aptian OAE1b multi-event. The microencrusters appeared during the upper part of a prolonged positive carbon isotope excursion in both carbon isotope records and can subsequently be linked to an increase in both sea surface temperatures and sea level.

In **chapter five** radiolitid rudist shells were evaluated for their ability to serve as a palaeoenvironmental archive, as stated in question (3), see p. 10. In order to test the suitability of these shells, sclerochronological analysis was combined with high-resolution geochemical sampling methods. Two right valves, a left valve plus its articulated right valve and a left valve were analysed. The left valve was shown to be a promising basis for palaeoenvironmental reconstructions, with regard to temperature and salinity. While the right valve is a suitable archive for habitat reconstructions.

**Chapter six** summarises the most important findings of this thesis and provides an outlook into future research.

## 2. Methodology

In the following chapter, the applied methodologies of this thesis are briefly presented, including fieldwork procedure, sample preparation and laboratory work. Furthermore, the usability of the analysed elements as tools for palaeoenvironmental reconstructions and their use as indicator for diagenetic alteration is described.

### 2.1 Field Work and Thin Section Microscopy

**Fig. 2.1:** Digital images of outcrop sites studied in this thesis: (A) Stars mark five samples (SL-9.5 to SL-11.5) taken with an average spacing of 0.5 m at the SL section. (B) Due to hampered outcrop conditions, the average sample spacing (A 33 to A 35) needed to be expanded to 1 m (stars).

During two field campaigns in November 2015 and March 2017, the 597 m-thick Santa Lucia (SL) section and the 469 m-thick Monte La Costa (MLC) section were logged and studied in detail. The carbonate classification scheme of Dunham (1962), modified by Embry and Klovan (1971) was applied for an outcrop-based carbonate facies description supported by petrographic analysis of polished slabs and thin sections. The fossil content of the samples was described, giving a particular focus to pristine rudist and chondrodont shells, non-skeletal components, subaerial exposure surfaces and karstic features. Samples for geochemical and petrographic investigations were taken at an average spacing of 0.5 m (Fig. 2.1 A). Across facies boundaries and discontinuity surfaces, a higher sample density was applied (spacing 0.1 m). Partially weathered outcrop conditions and accessibility obstructed the identification of bedding planes and other sedimentary features and sample spacing had to be widened to 1 m where necessary (Fig. 2.1 B).

Lithological and sedimentological analyses were supported by thin section analysis. A total of 131 thin sections of the SL section and 180 thin sections of the MLC section were prepared and analysed under a binocular. In addition, emphasis was laid on the identification and classification of microencrusting organisms (*Lithocodium-Bacinella*).

For bulk isotope analysis, all collected samples were cut, cleaned with distilled water and dried for 24 h at 40 °C. Rock specimens were screened with a magnifying glass to identify the most fine-grained portions, which were sampled with a hand-held micro-drill equipped with tungsten drill bits.

## 2.2 Isotope-ratio Mass Spectrometry (Gasbench)

The ratios of isotopes in open seawater equilibrate in a relatively short amount of time. Hence, long-term variations are interpreted as a global signal and are subsequently suitable for global and local correlations (Skelton et al., 2003). An added application lies in revealing the development of Earth's climate (hot and cold house episodes), the evolution of biota and the existence of diagenesis (Gradstein et al., 2012).

The carbon isotope record is based on the partitioning between organic carbonate and carbonate carbon reservoirs (e.g. Shackleton and Hall, 1984; Kump and Arthur, 1999; Sundquist and Visser, 2004) and is thus connected to the biosphere (Gradstein et al., 2012). Further processes that influence the carbon cycle are e.g. volcanic emission (Ridgwell and Edwards, 2007), the dissociation of methane clathrates (Dickens, 1995), continental weathering, upwelling, OAEs (Gradstein et al., 2012) or deep burial of carbon-rich rocks like carbonates or organic-rich mudstones (Skelton et al., 2003). Carbon isotope ratios are mostly used to correlate sediments (carbon isotope stratigraphy) (Weissert, 1989).

Variations in the oxygen cycle are mainly caused by climate changes, which make this isotope ratio, derived from calcite shells or from phosphatic fish skeletons, a valuable tool for its reconstruction: Lighter oxygen ( $^{16}\text{O}$ ) reacts faster than heavy oxygen ( $^{18}\text{O}$ ). During evaporation processes or the formation of ice, lighter oxygen escapes more easily and the residual water is enriched in heavy oxygen ( $^{18}\text{O}$ ), which increases its  $\delta^{18}\text{O}$  ratio.

An enrichment or depletion is expressed in the delta notation after Epstein (1951) that normalizes the isotope ratio to a selected standard:

$$\delta (\text{‰}) = \left( \frac{R_{\text{sample}}}{R_{\text{standard}}} - 1 \right) * 1000 \quad (1)$$

with  $R_{\text{sample}}$  and  $R_{\text{standard}}$  being the ratios of the sample and the standard reference material.

For this study,  $\delta^{13}\text{C}$  curves were primarily used to correlate shallow marine carbonate sections with pelagic sections and additionally to link various sections of the ACP. The analysed  $\delta^{18}\text{O}$  values, derived from the low-Mg calcite shells, were used for palaeotemperature reconstructions. Their combination (cross-plot) marked the influence of diagenetic alteration, which is applied to the highly fragmentary record of shallow marine sections and their included subaerial exposure surfaces of great importance. In total,  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  values of 1647 bulk and 502 shell samples were analysed using a Thermo Fisher Scientific Gasbench II carbonate device connected to a Thermo Fisher Scientific Delta 5 Advantage isotope ratio mass spectrometer at the stable isotope laboratory of the Institute of Geology,

Leibniz University Hannover, Germany. The gas bench uses viscous water-free ( $98 \text{ g mol}^{-1}$ ) orthophosphoric acid at  $72^\circ\text{C}$  to release  $\text{CO}_2$  of the calcitic sample material 1 h before the measurement is started. Repeated analyses of certified carbonate standards (NBS 19, IAEA CO-1, NBS 18 and Carrara Marble) show an external reproducibility of  $\leq 0.06 \text{ ‰}$  for  $\delta^{13}\text{C}$  and  $0.08 \text{ ‰}$  for  $\delta^{18}\text{O}$ . Values are expressed in conventional delta notation relative to the Vienna-Pee Dee Formation belemnite (VPDB) international standard, in parts per thousand (‰).

### 2.3 Trace Element Analysis and Strontium Isotope Analysis (SIS)

The  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio is used for a numerical age determination (McArthur, 2004) to elucidate the duration of gaps (Miller et al., 1988), to define biozones (McArthur et al., 1993) and stages (Weedon and Jenkyns, 1999) or to track changes in sedimentation rate (McArthur, 2007). It is assumed that the world's oceans are homogenous, which means that the residence time of Sr in the ocean ( $10^6 \text{ a}$ ) is higher than oceans mixing time ( $10^3 \text{ a}$ ). The variations in the  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of oceans are caused by the fact that continental rocks contain more  $^{87}\text{Sr}$  (relative to  $^{86}\text{Sr}$ ) than rocks derived from the mantle. Consequently, if continental weathering increases and/or oceanic volcanism decreases the  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of the ambient ocean water will increase. Previous studies have shown that the outer low-Mg calcite layer of Cretaceous rudist and chondrodont shells are suitable archives for the strontium isotope composition of contemporaneous ocean waters (Steuber et al., 2005; Frijia and Parente, 2008; Frijia et al., 2015; Huck and Heimhofer, 2015), enabling accurate age assignments of shallow marine strata by comparison with the global marine strontium isotope record (Howarth and McArthur, 1997; McArthur et al., 2001).

All found shells were cleaned, cut and dried like the bulk samples and afterwards selected by means of the following criteria:

1. well visible growth increments
2. fibrous microstructure of the compact outer shell layer
3. negligible impact of bioerosion and fracturing

Well preserved shells, classified as such by fulfilling aforementioned criteria, were used for further analysis. Their stable isotope ratios were measured as described above at the Institute of Geology, Leibniz University Hannover, Germany. For further analysis, powdered samples (1.35 to 1.65 mg) of 56 shells were analysed for their elemental composition (Ca, Mg, Sr, Fe and Mn) using inductively coupled plasma-atomic emission spectrometry (ICP-AES) at the isotope laboratory of the Institute of Geology, Mineralogy and Geophysics at Ruhr-University Bochum (RUB), Germany. Element concentration is used as proxy for evaluating the impact and degree of diagenetic alteration (Brand and Veizer, 1980). Re-equilibration processes with diagenetic fluids typically result in elevated Fe and Mn concentrations paired with low Sr concentrations (Brand and Veizer, 1980; Veizer, 1983; Al-Aasm and Veizer 1986; Steuber et al., 2005). A further indicator for diagenesis in rudist shells is a parallel decrease

in Mg concentration and  $\delta^{18}\text{O}$  values (Rauch, 2005; Marshall, 1992). 39 shells with < 100 ppm Mn and Fe concentrations (Steuber, 1999) and strontium concentrations > 800 ppm for rudists and > 500 ppm for chondrodonts (Steuber, 1999; Damas Mollá et al., 2006) were analysed at RUB for their strontium isotope ratios using a thermal ionisation mass-spectrometer (Finnigan MAT 262) in dynamic mode. Corrections of measured ratios to USGS EN-1 (rather than to NIST SRM987) were done following the procedure of Howarth and McArthur (1997).

## 2.4 $\mu\text{X}$ -ray Fluorescence

To analyse the preservation of shells, the  $\mu\text{XRF}$  scanning method was applied. This non-destructive method is used to characterize the abundance of different elements in the shell. A sample is radiated with an X-ray source and various elements are detected due to their emitted fluorescence. The measurements were performed at the research group Analytical, Environmental and Geochemistry of the Vrije Universiteit (Brussel) using a Tornado M4 micro X-ray fluorescence ( $\mu\text{XRF}$ ) scanner (Bruker Nano GmbH, Berlin, Germany). The  $\mu\text{XRF}$  scanner is equipped with a Rhodium source and two X Flash 430 Silicon Drift detectors.  $\mu\text{XRF}$  maps were created to allow a semi-quantitative analysis of the shell and an assessment of major and trace elements. Therefore, the entire polished shell surface was scanned using a short acquisition time of 1 ms per pixel. Quantitative point-by-point  $\mu\text{XRF}$  line scans were applied to each of the analysed shells, perpendicular to growth lamellae and following the growth direction (starting at the umbonal area). The average sampling space accounted 100  $\mu\text{m}$ . The X-ray beam dwelled on each point for 60 s at maximized energy settings (50 kV, 600  $\mu\text{A}$ , no source filter). Due to the growth form (morphology), various line scans were compiled to cover the entire shell. For further details, refer to de Winter and Claeys (2016) and de Winter et al. (2017). A total of 28 elements (Fig. 2.2) have been detected. This study focuses only on strontium (Sr), manganese (Mn), magnesium (Mg) and iron (Fe), which are the most important elements for the determination of diagenetic alteration (Steuber et al., 1999).

**Fig. 2.2:** Periodic table of elements with all the detected elements in the  $\mu$ XRF scans marked in orange. Elements considered in chapter 4 are marked in red (modified after Helmenstine, 2018).

## 2.5 Cathodoluminescence (CL)

To analyse the preservation state of a shell, cathodoluminescence (CL) microscopy was applied to polished thin sections and polished slabs. CL is a non-destructive tool to identify primary or diagenetic structures. In order to produce luminescence, the sample is bombarded with electrons. Main activators are  $Mn^{2+}$  and  $Pb^{2+}$  (orange-red luminescence), while  $Fe^{2+}$  acts as squeezer (no luminescence) (Flügel, 2010). CL was performed using a Reliontron (Relion, U.S.A) cold-cathode luminescence device hosted at the University of Texas in San Antonio (USA). The CL microscope is characterized by an acceleration voltage ranging from 10 to 15 kV and a current intensity ranging from 0.8 to 1.2 mA. The CL chamber was mounted on a Leica DM2700 microscope equipped with 2.5x, 4x, 10x and 20x magnification objectives.

### **3. Deciphering the Fragmentary Nature of Cretaceous Shallow-water Limestone Archives: A Case Study from the Subtropical Apennine Carbonate Platform**

K. SCHMITT, U. HEIMHOFER, G. FRIJIA, M. DI LUCIA, S. HUCK

*To be submitted to Newsletters on Stratigraphy.*

#### **Abstract**

Shallow-water carbonate platform sections are valuable archives for the reconstruction of deep-time environmental and climatic conditions, but the low resolution of biostratigraphic schemes associated with frequent sedimentary hiatuses often hampers their precise chronostratigraphic assignment. Moreover, chemostratigraphic correlation of shallow-water sections with well-dated pelagic successions is notoriously difficult and afflicted with large uncertainties, as shallow-water bulk carbonate archives are particularly prone to the impact of diagenesis. This study examines central Tethyan mid-Cretaceous carbonate platform deposits exposed in the central Apennines (southern Italy) suffering several emersion phases, which cause sedimentary gaps of variable duration. The investigated sections (Santa Lucia, Monte La Costa) represent a transect through the Apennine Carbonate Platform, ranging from the lagoonal inner carbonate platform realm towards the platform margin. Although benthic foraminifera are at times scarce and the carbonates evidently suffered diagenetic alteration, high-resolution carbon isotope stratigraphy combined with (rudist and chondrodont shell) strontium isotope stratigraphy enables a correlation of the studied sections with pelagic composite reference curves. A detailed foraminiferal-algal biostratigraphic record of the studied shallow-water sections and their integration into high-resolution carbon and strontium isotope stratigraphy is presented. This approach allows precise estimates of the time lost in major sedimentary hiatuses, three of which were identified at the Santa Lucia locality. There, long-lasting (1 to 14 Ma) hiatuses cover parts of the Early Aptian (3.2 Myr), the Late Aptian (3.3 Myr) and the Late Albian to Cenomanian (14.3 Myr), the latter being associated with formation of karst-filling bauxite. The here presented documentation and dating of sedimentary hiatuses in the Apennine Carbonate Platform sector is essential to correlate emersion phases observed in the peri-mediterranean region, in particular with respect to the mechanisms of their origin.

**Keywords:** Apennine carbonate platform (ACP); Cretaceous; Integrated bio-and chemostratigraphy; Emersion Phases

### 3.1 Introduction

During the mid-Cretaceous, widespread neritic carbonate deposition occurred in the Tethyan Ocean (Simo et al., 1993). Tropical carbonate factories formed large and complex sedimentary systems that document phases of extensive accumulation interrupted by growth crises related to environmental perturbations and/or tectonic activity (Skelton, 2003). Unfortunately, the assessment of shallow-water palaeoenvironmental variations on spatial and stratigraphic scales is often hampered by a limited resolution of applied biostratigraphic schemes and a lack of stratigraphic tie-points for correlation with well-dated pelagic successions (Frijia et al., 2015). The integration of chemostratigraphic (carbon and strontium isotopes) data into biostratigraphic frameworks significantly improves the temporal resolution of the Cretaceous shallow water rock record and furthermore helps to date and correlate strata on local and global scales, and across different depositional environments (Parente et al., 2007; Huck et al., 2013; Horikx et al., 2014; Frijia et al., 2015; Di Lucia et al., 2012; Raspini, 2012; Huck and Heimhofer, 2015). But even if shallow water carbonate archives may record secular and short-term carbon cycle changes of global extent, supra-regional chemostratigraphic correlation approaches are often hampered by strongly variable sedimentation rates and frequent subaerial exposure events, which produce significant stratigraphic gaps and thus, locally different carbon isotope patterns (Weissert et al., 2008; Di Lucia et al., 2012). Given the long residence time of strontium in the ocean, secular variations in  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios (McArthur et al., 2012) recorded in pristine low-Mg calcite shells enable to detect major sedimentary hiatuses ( $> 1$  Myr) and to estimate the time lost in the corresponding hiatal surfaces (Huck and Heimhofer, 2015; Navidtalab et al., 2016).

This paper seeks to illustrate and quantify the fragmentary nature of Cretaceous shallow water limestone archives, using the example of the central Apennine Carbonate Platform (ACP) in southern Italy. Both tectonic movements and eustatic sea level oscillations affected periadriatic shallow water carbonate platform environments during the Middle to Late Cretaceous (Carannante et al., 2007), amongst others expressed by two major emersion phases and associated karst bauxite (bx) formation. Both the Middle Albian to Middle Cenomanian and the Middle-Late Cenomanian to Late Turonian platform exposure episodes (bx1/bx2) are assumed to be mainly driven by local tectonic processes (D'Argenio and Mindszenty, 1995; Mindszenty et al., 1995). Estimating the duration of hiatuses of variable order in the Apennine shallow-water record, however, is not an easy task and in particular complicated due to the locally different impact of tectonic processes on carbonate sedimentation and preservation (D'Argenio et al., 2011).

The aim of this study is therefore to establish a highly resolved integrated bio-chemostratigraphic framework for two expanded shallow water sections representing both lagoonal and platform margin settings of the Central ACP. Special attention was paid to the assessment of sedimentary and geochemical data documenting major emersion phases. Most importantly, this

approach will allow estimating the time lost in major sedimentary gaps and identifying the (tectonic) processes causing platform exposure on a platform-wide scale.

### **3.2 Geological setting**

The Apennines are a fold-and-thrust belt extended along the Italian Peninsula, composed in large parts of thick Mesozoic shallow-water limestones deposited in the Tethyan domain (Fig. 3.1 A; Di Bucci, et al., 2006; Parente et al., 2007; Ruberti et al., 2008). The formation of these carbonate rocks (parts of them forming the ACP) started in the Late Triassic (Cosentino et al., 2010). Orogenic uplift was initiated in the Late Cretaceous/Eocene with the northward movement of the Adriatic/Apulian foreland (belonging to the African plate), resulting in the subduction of the Tethyan Ocean and subsequent collision with the Corsican/Sardinian foreland (Eurasian plate) (Vezzani et al., 2010; Cosentino et al., 2010). Carbonate sedimentation continued in the ACP until the end of the Miocene with huge gaps in the sedimentary record caused by the starvation in carbonate production and/or subaerial exposure through the uplift of the whole platform (Selli, 1957; 1962). Neogene folding and thrusting created complex imbricated units through low- and high-angle faults, which form the nappes stack of the Central and Southern Apennines (Brandano et al., 2007; Cosentino et al., 2010; Boncio et al., 2016).

The modern geological structure of the Central and Southern Apennines is the result of Quaternary extensional tectonics with a horst structure being bordered by NE - SW dipping normal faults (Boncio et al., 2016). The ACP represents a system of partly connected open shallow-water carbonate platforms (incl. Capri-Bulgheria, Alburno-Cervati and Monti della Maddalena Unit; Simbruini-Matese Unit; Western Marsica-Meta Unit) that were separated by basins and deep water tongues linking the Umbria domain and the Lagonegro-Molise Basin (Patacca and Scandone, 2007; Fig. 3.1 A).

The studied sections (Fig. 3.1 B) are located along a SE-NW proximal-to-distal transect across the ACP and represent the transition from lagoon (Santa Lucia, SL) towards a platform margin setting (Monte La Costa, MLC). The SL section is situated in the Southern Apennines in the Monte Cairo Massif (Lazio region) and belongs to the so-called Lazio-Abruzzi carbonate platform (Brandano, 2007). The 600 m-thick section is accessible along a road cut between Villa Santa Lucia and Terelle at the southern slope of Monte Cairo (41°31'00.6"N 13°46'40.0"E to 41°31'02.0"N 13°47'02.8"E). Chiocchini et al. (2004) investigated, most probably, the same section but measured a total thickness of only 420 m, which complicates an integration of their data into the current study.

**Fig. 3.1:** (A) Palaeogeographic map of the Upper Cretaceous showing the position of the study area of the Apennine Carbonate Platform (red circle). (B) Schematic geological map of the Central and Southern Apennines (Italy) with the location of the studied sections. 1 – Monte La Costa, 2 – Santa Lucia. Modified after Parente et al. (2007).

According to previous biostratigraphic observations based on benthic foraminifera and calcareous algae, the SL section covers the Hauterivian-Barremian to Upper Cenomanian interval (Chiocchini et al., 2004; Mancinelli and Chiocchini, 2006). The MLC section is located at the transition between the Central and Southern Apennines in the east-west oriented Matese Mountain Massif (Campania region). The 469 m-thick section (41°28'12.4"N 14°29'50.0"E) is located 1 km north of the village San Polo Matese. The section comprises platform margin shallow-water deposits of the Simbruini-Matese unit (Patacca and Scandone, 2007). Based on rudist and benthic foraminiferal biostratigraphy, the MLC succession has been attributed to the Barremian to Upper Cenomanian (Mainelli, 2000).

### 3.3 Field approaches and laboratory methods

#### 3.3.1 Field work and thin section microscopy

During a second field campaign, the existing SL and MLC section logs (Schmitt et al., in preparation) have been extended. The sedimentological characterization involved an outcrop-based carbonate facies description supported by the analysis of 204 petrographic thin sections (Fig. 3.2). Strongly weathered outcrop conditions at MLC often hampered the identification of bedding planes and other sedimentary features. Therefore, lithological and sedimentological analysis of the MLC section is mainly based on thin section analysis. Samples for geochemical and petrographic investigations were taken at an average spacing of 0.5 m. Higher sample densities were applied across facies boundaries and discontinuity surfaces.

**Fig. 3.2:** Photomicrographs of representative microfacies types observed in the studied sections. (A) Mud-/wackestone with rare benthic foraminifera and fragments of molluscs (sample A-30; height 30 m; section MLC). (B) Bioclastic grainstone with rounded clasts (sample SL-298; height 298 m; section SL). (C) Pack-/grainstone with benthic foraminifera, mollusc debris and

micropeloids (sample A-146; height 146 m; section MLC). (D) Rudstone composed of reworked subangular to well-rounded bioclasts (sample SL-319; height 319 m; section SL). (E) Carbonate breccia composed of variable clasts surrounded by a greenish to brownish, argillaceous matrix (sample B-17; height 464 m; section MLC). (F) Details of bauxitic level (bx1) with bauxite-filled karst cavities (sample SL2.2-8; height 514 m; section SL). (G) Bacinelloid boundstone (sample A-80; height 80 m; section MLC). (H) Densely packed oncoidal rudstone with oncoids of variable size (sample SL-368; height 368 m; section SL).

### 3.3.2 Carbon and oxygen isotope analysis

Bulk carbonate stable isotope results presented in Schmitt et al. (in preparation) were complemented by 950 additional bulk rock samples derived from the SL (n=487) and MLC (n=463) localities. Carbon and oxygen isotope analysis were performed in the stable isotope laboratory of the Institute of Geology, Leibniz University Hannover, Germany. All rock samples were cut, cleaned with distilled water and dried for 24 h at 40 °C. Rock specimens were screened with a magnifier to identify the most fine-grained portions, which were sampled with the help of a hand-held micro-drill equipped with tungsten drill bits. Large bioclasts, sparry cements and diagenetic calcite veins were avoided from being sampled.

Stable isotope analyses were conducted using a Thermo Fisher Scientific Gasbench II carbonate device connected to a Thermo Fisher Scientific Delta 5 Advantage isotope ratio mass spectrometer. The gas bench uses viscous water-free (98 g mol<sup>-1</sup>) orthophosphoric acid at 72°C to release CO<sub>2</sub> of the calcitic sample material 1 h before the measurement is started. Repeated analyses of certified carbonate standards (NBS 19, IAEA CO-1, NBS 18 and Carrara Marble) show an external reproducibility of ≤ 0.06 ‰ for δ<sup>13</sup>C and 0.08 ‰ for δ<sup>18</sup>O. Values are expressed in conventional delta notation relative to the Vienna-Pee Dee Formation belemnite (VPDB) international standard, in parts per thousand (‰). To facilitate the correlation of the chemostratigraphic curves, a five-point moving average was calculated from all the measured carbon- and oxygen isotope values of each studied section.

### 3.3.3 Element and strontium isotope analysis of low-Mg calcite shells

Special attention was paid to the collection of well-preserved low-Mg bivalve shells (chondrodonts and rudists) for strontium isotope stratigraphy (SIS). Although the limited size (<4 cm) of the collected rudist fragments has hampered a precise taxonomic classification, the observed celluloprismatic shell microstructure indicates that the majority of analysed shells belong to the rudist family Radiolitidae. The best-preserved shells were selected by means of the following criteria: (1) visible growth increments, (2) compact fibrous microstructure of the outer shell layer and (3) negligible impact of bioerosion and fracturing. Powdered rudist (n=38) and chondrodont (n=18) samples (1.35 to 1.65 mg) were analysed for their elemental composition (Ca, Mg, Sr, Fe and Mn) using inductively coupled plasma-atomic emission spectrometry (ICP-AES) at the isotope laboratory of the Institute of Geology, Mineralogy and Geophysics at Ruhr-University Bochum (RUB), Germany.

Strontium, iron and manganese abundances in rudist shells are used as proxies for evaluating the impact and degree of diagenetic alteration (Brand and Veizer, 1980). Selected samples (n=39) with low Mn and Fe concentrations (threshold value of < 100 ppm) and high strontium concentrations (threshold value of > 800 ppm for rudists (Steuber et al., 1999) and > 500 ppm for chondrodonts (Damas Mollá et al., 2006)) were analysed at RUB for their strontium isotope ratios using a thermal ionisation mass-spectrometer (Finnigan MAT 262) in dynamic mode (SL: Tab. 2.1: MLC: Tab. 2.2). For more details on the analytical procedure, refer to Huck et al. (2011). Corrections of measured ratios to USGS EN-1 (rather than to NIST SRM987) were done following the procedure of Howarth and McArthur (1997).

**Tab. 2.1:** Elemental composition and Sr-isotope ratios of selected low-Mg rudist and chondrodont shells of the SL section. The grey dataset was already published (Schmitt et al., in preparation).

### 3.4 Lithostratigraphy and carbonate microfacies

Based on characteristic microfacies associations, key biota and discontinuity surfaces, the 597 m-thick SL section can be divided into 5 lithostratigraphic units (I-V; Fig. 3.3). The lowermost unit (I: 0-199 m) is characterised by the prevalence of thin bedded lime mud- and wackestones showing common fenestral fabrics, voids filled with green argillaceous sediment and subordinate laminations. These mud-dominated portions alternate with oolitic grainstones and pack- and grainstones characterised by

laminoid fenestral fabrics (LF-BII type *sensu*; Flügel, 2010) and abundant calcimicrobes (hemispherical thalli of calcifying cyanobacteria) and/or algae (*Rivularia* sp., *Garwoodia* sp., *Hedstroemia/Cayeuxia* sp.; Mancinelli and Ferrandes, 2001). Lithostratigraphic marker levels include a dm-thick rudstone bed comprising densely packed large oncoids (at 123.5 m), reddish stylolites (161-173 m) and numerous cm- to dm-thick intra-formational karst-related breccias (48 m; 74 m, 93 m, 109-112 m, 115 m, 139 m, 142-145 m) characterised by angular clasts of limestone embedded in a greenish-brownish argillaceous matrix. The second unit (II: 199-236.5 m) is bound by brecciated levels and composed of mudstones (partly fenestral and laminated) containing sparse foraminifera and ostracods, and stratigraphically limited occurrences of calcimicrobes and dasycladacean algae (*Salpingoporella dinarica*). Reddish stylolites occur at two stratigraphic levels (200 m and 227.5 m). The unit III (236.5-332.5 m) is largely dominated by peloidal-bioclastic and foraminiferal grain- and rudstones bearing variable amounts of rudists (242-323 m), chondrodonts (271-280 m), nerineids (275 m), orbitolinids (286-312 m), solitary corals (313-324.5 m) and micritic oncoids (323.5-332 m) (Fig. 3.2 B and D). Mud-supported microfacies comprise (partly fenestral) miliolid-ostracod mudstones and wackestones and subordinate rudist floatstones (284-287 m). An interval characterised by the abundant occurrence (> 30% of the thin sections) of the dasycladacean green algae *S. dinarica* (248-265 m) is recorded beneath a well-exposed greenish karstic surface. Unit IV (333-516 m) is dominated by wacke- and floatstones containing common to abundant bacinelloid oncoids (Schmitt et al., in preparation) and gastropods that alternate with miliolid and bioclastic wackestones and subordinate grain- and floatstones bearing rudists (340-355 m, 419-436.5 m, 480 m, 513-515 m) and chondrodonts (370-387 m, 443.5 m). Densely packed oncoids of variable size (up to 5 cm in diameter) occur in rock-forming abundance at two stratigraphic levels (368-372.5 m, 392-394 m; Fig. 3.2 H). Further lithological marker levels include a reddish slightly brecciated palaeosoil (378.5-380 m) and a karst-related breccia characterised by angular mud-/wackestone clasts floating in a brownish-reddish slightly argillaceous matrix (443-443.5 m). Unit IV is bounded on top by a prominent brick-red bauxite level (514-516 m), which either occurs as massive layer or as complex system of multiple thin planar bauxite horizons and vertical bauxite-filled karst cavities (Fig. 3.2 F) that are interlocked with the rudist-bearing limestone host rock. In the uppermost part of the section (unit V: 516-597 m), two superordinate microfacies associations were differentiated. The first one comprises fenestral mudstones, which are frequently interrupted by coarser grained beds bearing variable amounts of oncoids and black pebbles. The second microfacies association is characterised by rapid facies changes, documented by alternations of thin mud-, wacke-, pack-, grain-, frame- and rudstone beds. The latter contain coral fragments, bacinelloid oncoids, green algae, gastropods, rudists and chondrodonts. Unfortunately, a comparably large part of unit V is covered by vegetation and weathering products (556-577 m). A calcareous karst breccia has been observed in the uppermost part of the section (586 m).

**Fig. 3.3:** Lithostratigraphy and high-resolution stable isotope stratigraphy of the Santa Lucia section. Chronostratigraphic calibration is based on the published data by Chiocchini et al. (2004). The therein mentioned bauxite level (bx1) is used as correlation point for the new findings of this work. The 597 m-thick profile can be divided into five lithostratigraphic units based on characteristic microfacies associations, key biota and discontinuity surfaces. A total of 16 samples were measured for SIS including 13 rudist (dark green asterisks) and three chondrodont (light green asterisks) shells. Classification of the rock samples follows Dunham (1962). Bold curves show the 5-point moving average of oxygen (blue) and carbon isotope (black) ratios with diamond symbols representing individual measured data points. Stratigraphic curves are subdivided into different segments (S1-S7) based on superimposed  $\delta^{13}\text{C}$  trends.

The MLC section can be divided into four different units (Fig. 3.4; I-IV). The lowermost unit (I: 0-66 m) is composed of mud- and wackestones bearing variable amounts of fragmented rudists and chondrodonts, dasycladacean algae and orbitolinids (Fig. 3.2 A), as well as rare intercalations of bioclastic pack- and grainstones and bacinelloid floatstones. Lithostratigraphical marker levels include numerous cm- to dm-thick intra-formational karst-related breccias (angular limestone clasts embedded in a greenish-brownish argillaceous matrix) and stratigraphic levels documenting a change towards pelagic conditions (laminated mudstone, mud- to wackestone bearing planktic foraminifers). Unit II (66-190 m) documents a switch towards higher energy well-sorted deposits, represented by grainstones with variable amounts of black pebbles, orbitolinids and further benthic foraminifers, rudists, gastropods and chondrodonts (Fig. 3.2 C). A remarkable feature of this unit is the abundant presence of bacinelloid boundstones (> 90% of the rock composition) that occur at thin section level as massive microencrusting network (Fig. 3.2 G). Furthermore, a conspicuous horizon (166-168 m) characterised by karstification features (mm-to cm-sized elongated dissolution features filled with micro-brecciated material) is observed. Unit III (190-372 m) is dominated by coarse-grained and often cement-rich rud- and grainstones (cementstone *sensu* Fagerstrom, 1987), which are composed of reworked subangular to well-rounded bioclasts (mainly radiolitid rudists, orbitolinids and bacinelloid oncoids) (Fig. 3.2 D). Muddier interbeds include gastropod and bacinelloid wacke- and floatstones and subordinate mud- and pack-/grainstones characterised by laminoid fenestrae. Repeated episodes of subaerial exposure are indicated by pendant cements and extensive dissolution features (mm-to cm-sized karst fractures, spherical cavities), the latter being filled either with greenish to brownish slightly argillaceous micrite or brecciated limestone material. A thin mudstone layer containing globigerinid foraminifers marks the onset of unit IV (372-469 m). This unit comprises strongly reworked well-sorted rud- and grainstones bearing well-rounded rudist bioclasts, which show evidence for partial to complete recrystallization (crystallites *sensu* Dunham). Compared to unit III the thickness of single beds is increased. A karst-related brecciated limestone level occurs between 462 and 464 m. The breccia is reworked, whitish limestone clasts vary in diameter from 3 cm to 0.2 cm and comprise Late Cretaceous (*Marginotruncana sp.*, *M. pseudolinneiana* and other keeled forms) and Tertiary planktonic foraminifera. The clasts show a rather angular form and they are clearly separated from the greenish to brownish slightly argillaceous matrix by a fine (~ 0.1mm), dark brown to reddish rim (Fig. 3.2 E).

**Fig. 3.4:** Lithostratigraphy and high-resolution stable isotope stratigraphy of the Monte La Costa section. Chronostratigraphic calibration is based on the published data by Mainelli (2000) and new findings of this work. The 469 m-thick profile can be divided into four lithostratigraphic units based on characteristic microfacies associations, key biota and discontinuity surfaces. A total of 22 samples were measured for SIS including 14 rudist (red asterisks) and eight chondrodont (orange asterisks) shells. Classification of the rock samples follows Dunham (1962). Bold curves show the 5-point moving average of oxygen (blue) and carbon isotope (black) ratios with diamond symbols representing individual measured data points. Stratigraphic curves are subdivided into different segments (M1-M5) based on superimposed  $\delta^{13}\text{C}$  trends.

### 3.5 Biostratigraphy

The stratigraphic range of identified benthic foraminifera and algae refer, among others, to widely used biostratigraphic schemes for the Central Apennine Platform (CAP) and the Adriatic Carbonate Platform (central Tethyan domain; Velic, 2007; Chiocchini et al., 2012; Di Lucia et al., 2012; Frijia et al., 2015). In Fig. 3.5, only those forms are plotted that are considered age-diagnostic.

**Fig. 3.5:** Microphotographs of selected age diagnostic microfossils from the studied sections, (A) *Pseudolituonella conica* (sample A-50; height 50 m; section MLC). (B) *Praechrysalidina infracretacea* (sample SL-323.5; height 323.5 m; section SL).

(C) *Cuneolina cf. sliteri* (sample SA-52; height 260 m; section MLC). (D) *Cribellopsis arnaudae* (sample SL2-160; height 500 m; section SL). (E) cf. *Haplophragmoides globosus* (sample A-103; height 103 m; section MLC). (F) *Moesiloculina danubiana* (sample A-100; height 100 m; section MLC). (G) *Salpingoporella dinarica* (sample SL-254.5; height 254.5 m; section SL). (H) *Dictyoconus cf. algerianus* (sample SA-117.5; height 325.5 m; section MLC). (I) *Pseudonummoloculina aurigerica* (SA-117.5; height 325.5 m; section MLC). (L) *Glomospira urgoniana* (sample A-76; height 76 m; section MLC). (M) *Carphatoporella occidentalis* (arrows) (sample MLC-21; height 372 m; section MLC). (N) *Mesorbitolina parva* (sample A-76; height 76 m; section MLC). (O) *Pseudorhapydionina dubia* (pb); *Cuneolina pavonia parva* (c), *Pseudolituonella reicheli* (pr) (sample SL2.2-82; height 589 m; section SL). (P) Different cuts of *Sellialveolina viallii* (sample SL2.2-20; height 526 m; section SL). White scale bar represents 200 µm. Black scale bar represents 1 mm.

In unit I of the SL section (Fig. 3.3), the benthic foraminifera content is represented by *Cuneolina camposaurii*, *Praechrysalidina infracretacea*, cf. *Neotrocholina friburgensis* (*sensu* Guillaume and Reichel, 1957), *Mayncina* sp. and *Cuneolina scarsellai*. Based on the occurrence of the dasycladacean algae *Salpingoporella cf. muehlbergii* (37 m) accompanied by *Salpingoporella* sp., the lower portion of unit I is associated with the Barremian part of the *C. camposauri* - *C. scarsellai* biozone of Chiocchini et al. (2012). The lack of age-diagnostic taxa in the remainder of unit I and the lower part of unit II (37-220 m) hampers a precise biostratigraphic age assignment. Unit II records the first occurrence (FO) of the dasycladacean alga *Salpingoporella dinarica* (221 m). Subordinate microfossils found within this unit comprise *Haplophragmoides* sp., *P. infracretacea*, *Salpingoporella* sp., *Moesiloculina* sp. and *Cuneolina scarsellai*. An Early Aptian age is suggested for this unit, corresponding to the *S. dinarica* biozone of Chiocchini et al. (2012). Unit III bears benthic foraminifera such as *Orbitolina* (*Mesorbitolina*) sp., *Sabaudia minuta*, *Sabaudia* sp., *Moesiloculina* sp., *Debarina hahounerensis*, *P. infracretacea*, *Cuneolina scarsellai*, *C. camposauri*, *Nezzazzata cf. isabellae*, *Spiroloculina* sp. and *Haplophragmoides cf. globosus*. Dasycladacean algae such as *Clypeina* sp., *Salpingoporella* sp., and *S. dinarica* are also observed. The co-occurrence of *S. dinarica* and *D. hahounerensis* at 254 m either indicates a Lower (Chiocchini et al., 2012) or Lower to Upper Aptian age (Di Lucia et al., 2012). The last occurrence (LO) of *S. dinarica* at 272.5 m is followed by the FO of *Nezzazzata cf. isabellae* at 276.5 m, which in the CAP is suggestive of an age not older than Late Aptian, biostratigraphically placed within the *Archeoalveolina reicheli* biozone of Chiocchini et al. (2012). Unit IV is characterised by the FO of high conical orbitolinids such as *Cribellopsis arnaudae* (343.5 m). Other observed benthic foraminifera include *P. infracretacea*, *P. aurigerica*, *C. pavonia/pavonia* var. *parva*, *C. laurenti*, *Nezzazzata* sp., cf. *D. algerianus*, *Moesiloculina histri* and large planispiral, porcellanaceous (LPP) forms. This foraminiferal assemblage can be correlated to the uppermost Aptian to lowermost Albian portion of the *D. algerianus* biozone of Chiocchini et al. (2012). The FO of *Cribellopsis cf. arnaudae* at 393 m is indicative of an Early Albian age (Chiocchini, 1989). Unit V comprises *?Pyrgo globulosa*, *Cisalveolina cf. lehneri*, *C. pavonia/pavonia* var. *parva*, *Nezzazzatinella* sp., *Pseudorhapydionina dubia*, *Pseudolituonella reicheli*, *Palaeosigmoilopsis apenninica*, *Sellialveolina viallii*, *Spiroloculina cenomana* and *Trochospira avnimelechi*. Whereas the occurrence of *S. vialli* at 523 m points to an intra-Lower (Chiocchini et al., 2012) to Middle Cenomanian (De Castro, 1985), an intra-Lower to intra-Upper Cenomanian is indicated by the sole occurrence of *Trochospira*

*avnimelechi* at 537 m. The LO of *S. cenomana* and coeval FOs of *P. dubia* and *P. apenninica* at 555m suggest the Middle to Upper Cenomanian (Chiocchini et al., 2012). The stratigraphically youngest thin section sample (587 m) yields the sole occurrence of *P. reicheli*, a form that is indicative for the Upper Cenomanian. In light of the foraminiferal occurrences described above, unit V arguably ranges from the uppermost part of the Ostracoda and Miliolidae to the *C. gradata*-*P. reicheli* biozones (refer to Chiocchini et al., 2012).

Unit I (Fig. 3.4) of the Monte La Costa section comprises benthic foraminifera such as *H. cf. globosus*, *?Earlandia conradi*, *Bulimina* sp.?, cf. *Dobrogeolina ovidi*, *Quinqueloculina* sp., *Glomospira* sp., *Istriloculina elliptica*, *Orbitolina* (cf. *Mesorbitolina*) sp., *Moesiloculina* cf. *danubiana*, *Nezzazzatinella* sp., *P. infracretacea*, *Pseudolituonella conica*, *Cuneolina* sp., *Spiroloculina* sp. and dasycladacean algae including *Triploporella marsicana*. Whereas *T. marsicana* (8-13 m) and *P. conica* (50 m) are reported from Lower Aptian shallow water deposits in the CAP, the occurrence of *Orbitolina* (*Mesorbitolina*) sp. at 5 m indicates an intra-Lower to Upper Aptian age, biostratigraphically positioned between the *S. dinarica* and the *A. reicheli* biozones of Chiocchini et al. (2012). Microfossils identified in unit II include *Glomospira urgoniana*, *Sabaudia* sp., *Cuneolina* sp., *Spiroloculina* sp., *Moesiloculina histri*, *Coptocampylodon fontis*, *Istriloculina* cf. *eliptica*, *Quinqueloculina* sp., cf *Moesiloculina danubiana*, *?Nezzazzatinella* sp., *Cuneolina laurentii*, *Pseudolituonella conica*, *Trochamminoides* cf. *coronus*, *Nezzazata isabellae*, *Haplophragmoides* cf. *globosus*, *Orbitolina* (cf. *Mesorbitolina*) sp. and LPP forms. In the CAP, the FO of the ‘incertae sedis’ taxon *Carphatoporella occidentalis* (76 m) is indicative of an age not older than Late Aptian (*A. reicheli* biozone of Chiocchini et al., 2012). This age assignment is supported by the LO of *P. conica* at 150 m and the FO of *Nezzazata isabellae* at 188 m.

Unit III comprises benthic foraminifera such as *Cuneolina laurentii*, cf. *Glomospira* sp., *Orbitolina* (cf. *Mesorbitolina*) sp., *Istriloculina* cf. *elliptica*, *C. fontis*, *Cribellopsis* cf. *arnaudae*, *Cuneolina* cf. *sliteri*, cf. *Dictyoconus algerianus*, *Moesiloculina histri*, *Nezzazata isabellae*, *Pseudonummoloculina aurigerica*, *Sabaudia* sp., *Cuneolina pavonia/pavonia* var. *parva*, *P. infracretacea*, LPP forms and the dasycladacean algae *Russoella radoicicae*. The association of *R. radoicicae* with *C. fontis*, *Orbitolina* (cf. *Mesorbitolina*) sp. and the FO of *P. aurigerica* at 210 m is indicative of an age not older than Early Albian in the CAP, biostratigraphically placed around the boundary between the *A. reicheli*/*D. algerianus* and Ostracoda and Miliolidae biozones of Chiocchini et al. (2012). A lower Albian age of the upper part of unit III is supported by the FO of *C. arnaudae* at 261 m and *D. algerianus* between 324 m and 371 m (Chiocchini, 1989; Chiocchini et al., 2012).

Benthic foraminifera identified in unit IV include *Cuneolina* sp., *C. pavonia/pavonia* var. *parva*, *Orbitolina* (cf. *Mesorbitolina*) sp., *P. infracretacea*, cf. *Nummoloculina*, *P. aurigerica*, *Quinqueloculina* sp., *N. isabellae*, *C. fontis*, *Moesiloculina* sp. and LPP forms. This foraminiferal assemblage suggests an age not younger than Early Albian, biostratigraphically placed within the lower part of the Ostracoda and Miliolidae biozone of Chiocchini et al. (2012).

## 3.6 Geochemical results

### 3.6.1 Bulk carbonate carbon- and oxygen isotope stratigraphy

Bulk carbonate  $\delta^{13}\text{C}$  values of samples derived from the SL section (Fig. 3.3) vary between -3.63 and 4.46 ‰ (mean: 2.2 ‰). Based on superimposed trends, the  $\delta^{13}\text{C}$  record is divided into seven chemostratigraphic segments (S1-7). Segment S1 (0-46 m) exhibits  $\delta^{13}\text{C}$  values fluctuating around a background value of about 2 ‰. Segment S2 (46-118 m) displays a well-expressed positive carbon isotope excursion (CIE) with an amplitude of about 1 ‰ that is terminated by a negative  $\delta^{13}\text{C}$  spike. The following segment S3 (118-265 m) is composed of multiple negative and positive excursions that are superimposed on a trend towards more positive  $\delta^{13}\text{C}$  values. Separated by a sharp negative  $\delta^{13}\text{C}$  spike reaching  $\delta^{13}\text{C}$  values of 0.1 ‰ (263 m), segment S4 (265-335 m) comprises rather strong  $\delta^{13}\text{C}$  fluctuations that are superimposed on a stepwise positive shift reaching peak values of 4.3 ‰. A sharp negative carbon isotope spike marks the onset of segment S5 (335-390 m). This segment displays oscillating  $\delta^{13}\text{C}$  values with average amplitudes of about 1 ‰, which are followed by an expanded moderately positive  $\delta^{13}\text{C}$  bulge reaching 2.9 ‰ (S6: 390-480 m). The topmost segment S7 (480-596 m) appears as pronounced stepwise negative  $\delta^{13}\text{C}$  shift, characterised by strongly fluctuating values and numerous negative spikes reaching values of -1.1 ‰.

Oxygen isotope values of bulk carbonates of the SL section range from -5.19 to 0.2 ‰ (mean: -1.9 ‰). The lowermost part of the  $\delta^{18}\text{O}$  record (0-100 m) displays strongly variable values forming a plateau. A sharp negative shift marks the onset of the following chemostratigraphic segment that shows a stepwise trend towards more positive values (100-265 m). An expanded negative trend is observed in the remaining part of the  $\delta^{18}\text{O}$  record (265-587 m), only interrupted by a short interlude (335-350 m) providing enhanced oxygen isotope values.

Bulk carbonate  $\delta^{13}\text{C}$  values of the MLC section (Fig. 3.4) range between -1.51 and 4.86 ‰ (mean: 2.7 ‰). Superimposed  $\delta^{13}\text{C}$  trends and inflection points enable distinguishing five chemostratigraphic segments (M1-5). Limestones of the lower part of the section (segment M1: 0-32 m) record a short negative  $\delta^{13}\text{C}$  shift (as low as 1.22 ‰ at 30 m) followed by a long-term expanded positive  $\delta^{13}\text{C}$  shift reaching values of up to 4.86 ‰ (M2: 32-118 m). Notably, the lower part of segment M2 is characterised by strong  $\delta^{13}\text{C}$  fluctuations. A sharp negative carbon isotope spike at 118 m marks the onset of the following segment M3 (118-202 m). Carbonates representing this segment record a saw-tooth shaped  $\delta^{13}\text{C}$  pattern with multiple fluctuations (amplitude: < 0.8 ‰) that are superimposed on a negative trend. The following chemostratigraphic segment M4 displays a carbon isotope plateau with strongly oscillating values (202-382 m). Limestones representing the uppermost part of the MLC section (M5: 382-469 m) record multiple negative  $\delta^{13}\text{C}$  shifts that represent the lowest values of the  $\delta^{13}\text{C}$  curve (-0.9 ‰ at 423 m).

Oxygen isotope values recorded by limestones of the MLC section vary between -4.94 and 0.1 ‰ (mean: -2.6 ‰). The lower part of the  $\delta^{18}\text{O}$  curve (0-142 m) records alternating negative and

positive excursions (amplitudes < 2 ‰) that are superimposed on a negative trend. Up-section, the oxygen isotope curve exhibits an expanded plateau interval characterised by values fluctuating around background values of about -2.4 ‰ (142-406 m). The uppermost part of the  $\delta^{18}\text{O}$  curve (406-469 m) displays a very pronounced negative trend reaching minimum values of -5.04 ‰ at 455 m, which is followed by an abrupt positive  $\delta^{18}\text{O}$  shift (0.1 ‰ at 465 m).

### 3.6.2 Trace element and strontium isotope results

Rudist shells derived from the Santa Lucia (Tab. 2.1; n=16) and Monte La Costa sections (Tab. 2.2; n=22) provide magnesium concentrations varying between 565 and 3814 ppm (mean: 2135 ppm; s.d.: 744 ppm), strontium concentrations varying between 199 and 1573 ppm (mean: 971 ppm; s.d.: 346 ppm), iron concentrations varying between 2 and 331 ppm (mean: 23 ppm; s.d.: 53 ppm) and manganese concentrations varying between 0.9 and 36 ppm (mean: 5 ppm; s.d.: 8 ppm). Analysed chondrodont shells (Tab. 1: SL n=8; Tab. 2: MLC n=10) yield magnesium concentrations ranging from 2132 to 3708 ppm (mean: 2966 ppm; s.d.: 383 ppm), strontium concentrations ranging from 414 to 1183 ppm (mean: 650 ppm; s.d.: 208 ppm), iron concentrations ranging from 2 to 46 ppm (mean: 13 ppm; s.d.: 13 ppm) and manganese concentrations ranging from 1 to 56 ppm (mean: 7 ppm; s.d.: 12 ppm). Chondrodont and rudist shells selected for strontium isotope analysis (n=39) are characterised by average strontium abundances of 756 ppm (s.d.: 193 ppm) and 1138 ppm (s.d.: 161 ppm) and generally low iron (mean: 11 ppm; s.d.: 15) and manganese (mean: 3 ppm; s.d.: 3) abundances.

The SIS record of the SL section (including data presented in Schmitt et al, in preparation) is based on selected rudist (n=14) and chondrodont shells (n=3). The obtained SIS pattern mimics the overall Late Barremian to Early Albian evolution in marine strontium isotope ratios. During this interval, the  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of marine carbonates is characterised by a long-term decreasing trend with minimum  $^{87}\text{Sr}/^{86}\text{Sr}$  values during the latest Aptian and a subsequent positive trend towards the Albian-Cenomanian. Notably, a rudist shell located directly above a well-expressed karst breccia records the most radiogenic  $^{87}\text{Sr}/^{86}\text{Sr}$  value ( $0.707482 \pm 7 \cdot 10^{-6}$ ). Rudist (n=14) and chondrodont (n=8) shells of the MLC section (including data presented in Schmitt et al., in preparation) record moderate  $^{87}\text{Sr}/^{86}\text{Sr}$  fluctuations that are superimposed on an increasing trend towards more radiogenic values ( $0.707273 \pm 7 \cdot 10^{-6}$  to  $0.707420 \pm 5 \cdot 10^{-6}$ ). Shells from the stratigraphically uppermost part of the section document a decline in  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios ( $0.707420 \pm 5 \cdot 10^{-6}$  to  $0.707369 \pm 5 \cdot 10^{-6}$ ).

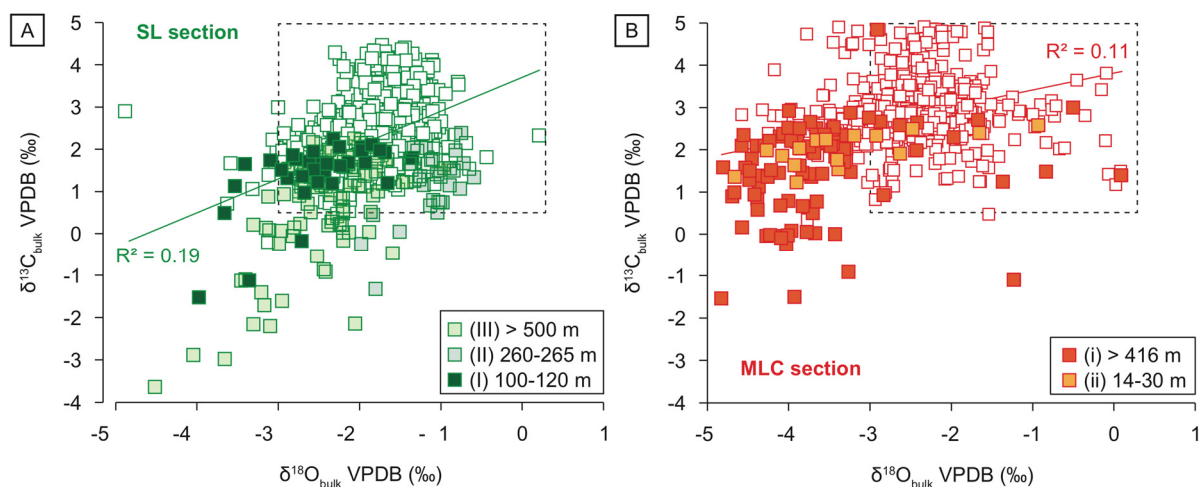

## 3.7 Discussion

### 3.7.1 Significance of bulk carbonate and bivalve shell chemostratigraphic patterns

High-resolution chemostratigraphy has become an indispensable tool for stratigraphic correlation of Mesozoic (hemi-) pelagic and shallow-water deposits (Weissert, 1989; Jenkyns et al., 1994; Menegatti

et al., 1998; Godet et al., 2006; Parente et al., 2007; Weissert et al., 2008; Huck et al., 2011; Navidtalab et al., 2016). However, marine stable isotope signatures can be influenced by a multitude of environmental and post-depositional processes that will produce significant offsets from the global open marine primary signals (Hudson, 1977; Brand and Veizer, 1981; Allan and Matthews, 1982; Veizer, 1983; Lohmann, 1988; Immenhauser et al., 2008; Huck et al., 2017; Oehlert and Swart, 2014; Swart, 2015). Shallow-water carbonate platform settings are particularly prone to syn- and post-depositional alteration of stable isotope signatures due to (1) the high primary porosities of shallow-water bioclastic deposits and (2) the likeliness of subaerial exposure associated with sea level changes (Immenhauser et al., 2003; Strasser, 2015). Bulk carbonate oxygen isotope values often show evidence for diagenetic alteration, but can help to unravel the composition and temperature of involved diagenetic fluids (Brand and Veizer, 1981). Carbon isotope values, in contrast, are usually rock buffered and therefore more resilient (Moore, 1985).

Cross-plots of bulk carbonate  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values (Fig. 3.6) document that the majority of analysed bulk carbonate isotope values (SL: 94%, MLC: 77%) overlap with the field of Barremian-Aptian low-latitude biotic calcite (Prokoph et al., 2008). The low covariance between carbon- and oxygen isotope values (SL:  $R^2 = 0.19$ ; MLC:  $R^2 = 0.11$ ) suggests that most samples are well preserved. A moderately (SL section) to well expressed (MLC section) ‘inverted J’ stable isotope pattern, however, indicates a stratigraphically limited impact of meteoric diagenesis (Brand and Veizer, 1980; Allan and Matthews, 1982; Lohmann, 1988; Jones et al., 2015). Thin section inspection of samples derived from the stratigraphic levels SL: I: 100-120 m, II: 260-265 m, III > 500 m; MLC: i: > 416 m, ii: 14-30 m (Fig. 3.6) indeed reveal the occurrence of spar-filled fenestral fabrics, voids filled with green argillaceous micrite, vertical bauxite-filled karst cavities or karst-related intra-formational breccias – features typically associated with subaerial exposure episodes (Flügel, 2010; Raspini et al., 2012; Godet et al., 2016; Navidtalab et al., 2016).

**Fig. 3.6:** Cross-plots of  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  values of bulk carbonate samples from the (A) Santa Lucia and (B) Monte La Costa sections. The grey square shows the average isotopic range of shallow marine tropical-subtropical carbonates compiled by the data of well-preserved biotic calcite from the Barremian-Aptian (modified after Di Lucia et al., 2012 from Prokoph et al.,

2008). Both diagrams show low covariance (SL:  $R^2 = 0.19$ ; MLC:  $R^2 = 0.13$ ). The isotopic compositions of some bulk carbonate samples, especially the ones below exposure surfaces (filled), provide evidence for diagenetic alteration under meteoric or shallow marine conditions.

Previous studies have demonstrated that the outer low-Mg calcite layer of Cretaceous rudist and oyster shells is a suitable archive for the strontium isotope composition of contemporaneous ocean waters (Steuber et al., 2005; Frijia and Parente, 2008; Burla et al., 2009; Schneider et al., 2009; Horikx et al., 2014; Frijia et al., 2015; Huck and Heimhofer, 2015), enabling accurate age assignments of shallow marine strata by SIS (Howarth and McArthur, 1997; McArthur et al., 2001; McArthur et al., 2012). Oysters typically inhabit coastal settings that are often characterised by radiogenic  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios associated with riverine siliciclastic input (Schneider et al., 2009). Thus, the interpretation of strontium isotope signals recorded by oyster-like chondrodont bivalves (Stanton, 1901; Ayoub-Hannaa and Fürsich, 2011) is not devoid of problems, in particular since comparably less is known about the palaeoecology and geochemistry of these extinct bivalves.

In general, both rudist and chondrodont shells show well-preserved growth increments at the macroscopic scale. Thin sections inspection, however, reveals that the microstructure of radiolitid rudists is, as expected, highly variable along shell sections, ranging from compact fibrous to celluloprismatic microstructures. In accordance with published elemental threshold values (Steuber et al., 2005; Frijia and Parente, 2008; Frijia et al., 2015), only compact rudist shell portions with Fe and Mn concentrations below 100 ppm and Sr concentrations exceeding 800 ppm are considered for SIS (Fig. 3.7 A). A cross-plot of Mg and Sr contents illustrates that values provided by selected pristine rudist shells plot closer to the regression line of biotic calcite than of abiotic calcite (Fig. 3.7 B; Carpenter and Lohmann, 1992; Steuber, 1999). Measured Mg (mean: 1919 ppm) and Sr contents (mean: 1138 ppm) largely overlap with those reported for compact fibrous shell portions of the radiolitid rudist *Gorjanovicia cf. costata*, but clearly deviate from those of the radiolitid rudist *Durania aff. mutabilis*, whose outer shell layer often comprises honeycomb-type structures filled with diagenetic low-Mg calcite (Fig. 3.7 B; Steuber 1999). Finally, a pristine preservation state of rudists is supported by  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values, which show no correlation (Fig. 3.7 C;  $R^2 = 0.004$ ).

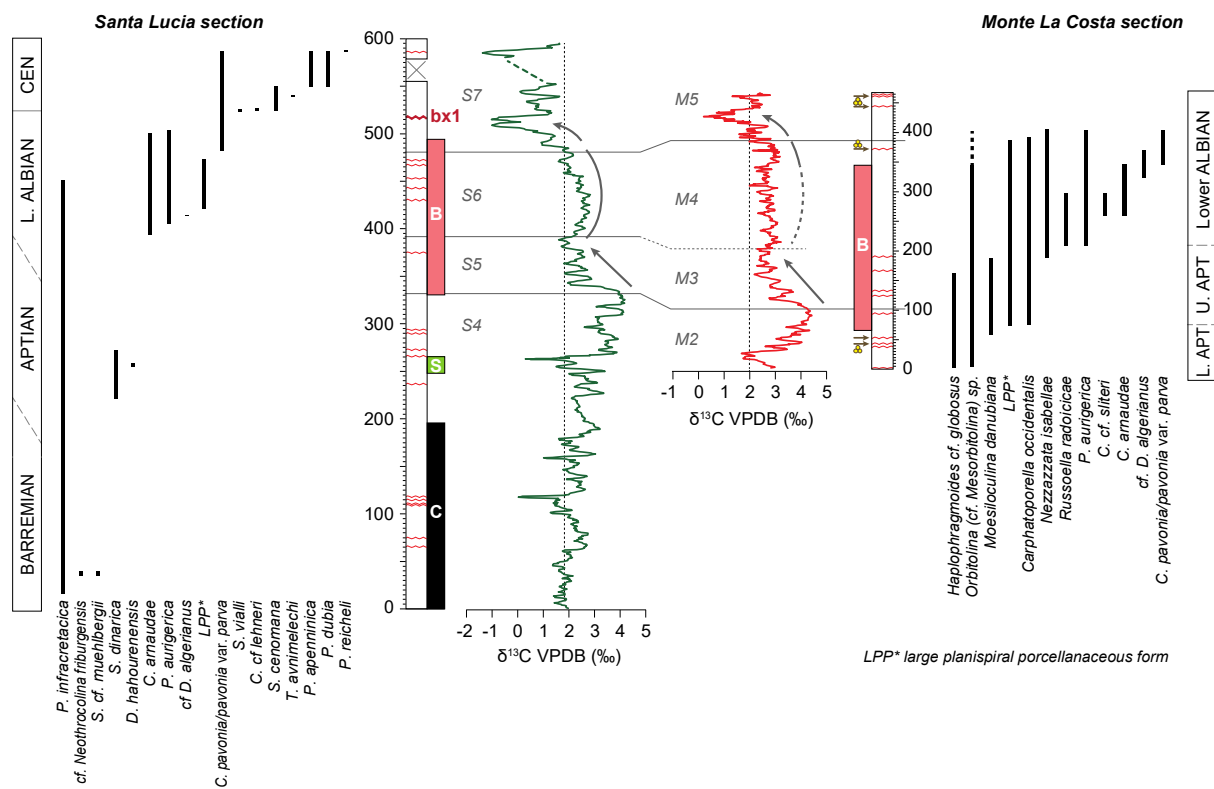

Fig. 3.7: Isotope and elemental compositions of bivalve shells derived from the SL and MLC sections (circle: rudist; triangle:

chondrodont). (A) The concentration of Sr and Mn is decisive for further analyses of the samples. Is the Sr concentration under a certain threshold (stippled line for rudists < 800 ppm; dashed line for chondrodonts < 500 ppm) the shell is excluded for further analyses (marked by a red frame and yellow filling). (B) Mg and Sr compositions of rudist and chondrodont shells compared with mean compositions of modern biotic (top line) and abiotic (bottom line) marine calcite (Carpenter and Lohmann 1992; Steuber 1999). For comparison published data derived from (a) an diagenetically unaltered radiolitid (*Gorjanovicia* cf. *costata*), (b) an altered *Durania* aff. *mutabilis* radiolitid (red; Steuber, 1999) were plotted. Red horizontal and vertical lines mark the ranges of these datasets (a: number of samples: 19; b: number of samples: 24). Dataset of a chondrodont is indicated by a solid pink triangle (Damas Mollá, 2006; 2009) (C) Cross-plot of  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  values showing low covariance for rudists ( $R^2= 0.004$ ) indicates the absence of strong diagenetic alteration of the isotopic signal. The chondrodonts show a high covariance ( $R^2=0.22$ ) but compared to the dataset of Damas Mollá (2006; 2009) (pink triangles) they are plotting in a similar range.

According to a sclerochemical study of an Albian chondrodont shell from northern Spain, elemental compositions of chondrodonts are highly variable, with Sr contents of pristine portions of the shell ranging from 500 to 2000 ppm and Mn contents ranging from 10 to 250 ppm (Damas Mollá et al., 2006). Chondrodont shells with Sr concentrations below 500 ppm and Mn concentrations above 250 ppm are therefore not considered for SIS (Fig. 3.7 A). In line with the results obtained by Damas Mollá et al. (2006; 2009), most of the selected chondrodont shells reveal a low to moderate positive correlation of carbon and oxygen isotope ratios (Fig. 3.7 C;  $R^2=0.22$ ).

### 3.7.2 Integrated bio- and chemostratigraphic dating

Age diagnostic benthic foraminifera and algae provide evidence that SL limestones are of Barremian to Late Cenomanian age. The MLC section is biostratigraphically attributed to the Late Aptian and Early Albian. In order to increase the stratigraphic precision of the identified foraminiferal-algal assemblages, a platform-wide carbon isotope based correlation of the studied sections is carried out, followed by SIS. The Aptian portions of both curves display a negative peak and a subsequent prominent positive excursion, which comprises the most positive carbon isotope values in both sections (Fig. 3.8: segments S4 and M2). The following interval is characterised by strongly variable but rather cyclic  $\delta^{13}\text{C}$  changes that are superimposed on an overall negative trend (Fig. 3.8; segments S5 and M3). While the Albian portion of the SL section displays a low-amplitude positive carbon excursion (Fig. 3.8: S6), coeval sediments of the MLC section record fluctuating  $\delta^{13}\text{C}$  values that are superimposed on a minor positive excursion (Fig. 3.8: segment M4). A strongly pronounced stepwise negative excursion characterises the uppermost portion of both sections (Fig. 3.8: segments S7 and M5).

**Fig. 3.8:** Bio- and isotope stratigraphy of the SL (green) and the MLC (red) sections. Both  $\delta^{13}\text{C}$  curves show a similar pattern with stratigraphic height. The appearance of calcimicrobes (C), *Salpingoporella dinarica* (S), bacinelloids (B), bauxite (bx1) and Globigerinids ( $\clubsuit$ ) are marked.

The carbon isotope pattern of both sections allows for a correlation with well-dated pelagic carbon isotope reference records. However, refinement of the biostratigraphic dating in the central and southern Apennines solely based on carbon isotope correlation is hampered by the occurrence of sedimentary hiatuses in the studied SL section. Carbon isotope stratigraphy is therefore improved and calibrated by means of SIS (McArthur et al., 2012) and subsequently compared with biostratigraphic data (Fig. 3.9). Due to the expanded stratigraphic range of the SL and MLC sections, two different pelagic carbon isotope reference records were compiled from literature (Fig. 3.9). The first composite record is based on  $\delta^{13}\text{C}$  data derived from the Umbria Marche Basin in Italy (Sprovieri et al., 2006; Giorgioni et al., 2012; Bottini et al., 2015; Erba et al., 2015; Gambacorta et al., 2015), adjacent to the here studied ACP. The second composite carbon isotope record comprises data from the Vocontian Basin in southeastern France (Gale et al., 1996; Herrle et al., 2004; Godet et al., 2006; Gyawali et al., 2017). Notably, the hemipelagic deposits of the latter basin bear numerous belemnites providing a high-resolution strontium isotope stratigraphic framework (Bodin et al., 2009; Bodin et al., 2015). Both composite isotopic records were tied to the GTS2012 timescale (Gradstein et al., 2012) by integrating multiple stratigraphic information including ammonite and foraminiferal biostratigraphy, chemostratigraphy, sequence stratigraphy, magnetostratigraphy and lithostratigraphy (i.e., organic-rich levels associated with OAEs).

Basin (black; Sprovieri et al., 2006; Giorgioni et al., 2012; Bottini et al., 2015; Erba et al., 2015; Gambacorta et al., 2015) and the Vocontian Basin (brown; Gale et al., 1996; Herrle et al., 2004; Godet et al., 2006; Gyawali et al., 2017). The chronostratigraphic ages of the pelagic curves are based on foraminifera and ammonite data plotted against the GTS 2012 (Gradstein et al., 2012), while the SL and the MLC sections are correlated using biostratigraphic information combined with C- and Sr-isotope data. Global sea level changes after Haq 2014.

Strontium isotope values derived from the lower part of the SL section (mean: 0.707478; n=2) indicate an age not younger than early Late Barremian (McArthur et al., 2012). The corresponding stratigraphic interval (60-85 m) is characterised by a positive CIE that tentatively represents the mid-Barremian Event (MBE; Huck et al., 2013; Huck and Heimhofer, 2015). The following stepwise shift to more positive carbon isotope values is a typical Late Barremian-earliest Aptian feature of pelagic sections in the Umbria Marche (Gorgo a Cerbara: Sprovieri et al., 2006) and Vocontian basins (Angles: Godet et al., 2006). In line with previous shallow-water chemostratigraphic results from the Southern and Central Apennines (Di Lucia et al., 2012), the carbonate platform production at the SL locality came to a halt in the prelude of the Oceanic Anoxic Event (OAE) 1a. This is indicated by a dm-thick brecciated interval and the absence of the characteristic positive  $\delta^{13}\text{C}$  excursion associated with OAE1a. Following biostratigraphic (*Salpingoporella dinarica*) and SIS evidence ( $^{87}\text{Sr}/^{86}\text{Sr}$ : 0.707293) recorded by SL limestones, the recovery of the carbonate platform factory (248-265 m) took place during the Late Aptian. Upsection another hiatus in the sedimentary record is indicated both by a prominent subaerial exposure surface and a rapid decline in  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios (see also Huck and Heimhofer, 2015) toward values typical for the latest Aptian (mean: 0.707194).

A prominent feature of both the SL and MLC carbon isotope curves is an interval with fluctuating but overall positive  $\delta^{13}\text{C}$  values (SL: 160-385 m; MLC: 52-160 m) that is terminated by a sharp negative shift. Strontium isotope data derived from the SL section (0.707235 to 0.707194) clearly suggest that this chemostratigraphic segment correlates with the lower part of the OAE1b multi-event, stratigraphically positioned between the Jacob and Kilian levels (Schmitt et al., in preparation). Considering strontium isotope results, the  $\delta^{13}\text{C}$  inflexion point marked by the most negative values at MLC corresponds to the Leenhardt episode of OAE1b. In the Vocontian and Umbria Marche carbon isotope records, the Kilian 'black-shale' interval is preceded by negative  $\delta^{13}\text{C}$  spikes superimposed on a 1 ‰ negative CIE (Leckie et al., 2002; Erba et al., 2015; Herrle et al., 2004). As already documented by Schmitt et al. (in preparation), the coeval onset of pervasive bacinelloid microencruster growth in both the inner (SL) and marginal (MLC) carbonate platform domain during the upper part of the positive CIE (plateau phase) supports the abovementioned chemostratigraphic correlation.

A pronounced increase in  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios (0.707273 to 0.707420) is visible in bivalve calcite collected from post-Kilian limestones at SL and MLC. This pattern is a typical Early to Middle Albian feature of the global marine strontium isotope curve (McArthur et al., 2012). Unfortunately, sediments from above the bauxite level bx1 do not contain low-Mg calcite shell material suitable for SIS. The

foraminiferal assemblage comprising *P. reicheli*, *P. dubia* and *P. apenninica*, however, clearly indicates a Middle to Late Cenomanian age for the uppermost part of the SL section.

### 3.7.3 Time lost in discontinuity surfaces

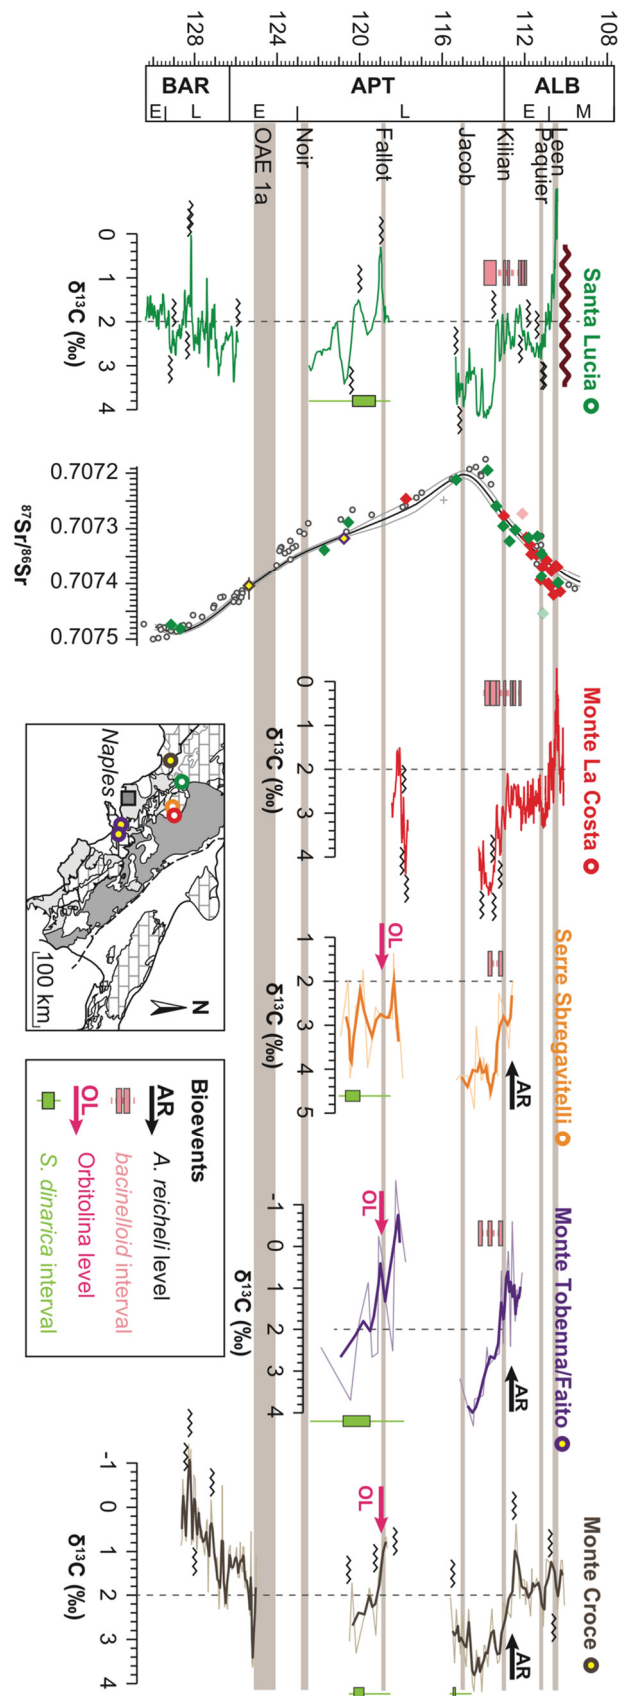

The fragmentary nature of marine sedimentary archives is a well-known phenomenon that is largely governed by a net loss of accommodation space and associated periods of mechanical erosion, condensation, non-deposition and/or chemical dissolution (Ager, 1973; Sadler, 1981; Strasser, 2015). Hiatuses in the depositional record of shallow sedimentary environments are particularly abundant and result from both short-term peritidal processes (e.g. scouring of tidal channels) and long-term sea level fluctuations, the latter being represented by major sequence boundaries (Strasser, 2015). Assessing the frequency and duration of shallow water sedimentary hiatuses is therefore almost impossible, although long-term carbonate platform emersion episodes (> 1 Myr) have the chance to be faithfully depicted by means of SIS (McArthur et al., 2001; Navidtalab et al., 2016).

The here presented integrated bio-chemostratigraphic framework of the central ACP Santa Lucia succession (Fig. 3.9) reveals that about 61% of the time (~ 20.7 Myr) is lost in three major hiatal surfaces incl. intervals of the Early Aptian (~ 3.2 Myr), Late Aptian (~ 3.3 Myr) and Middle Albian to uppermost Middle Cenomanian (~ 14.2 Myr). The Late Aptian hiatus is also recorded by the stratigraphically less expanded MLC section. Using the established stratigraphic framework, correlations and/or comparisons of several hiatuses across the platform are possible.

At the SL locality, large parts of the Early Aptian sedimentary record are missing. The corresponding hiatal surface (Fig. 3.3, 236 m), which is estimated to cover 3.2 Myr, appears as thin brecciated interval and is located at the transition from predominantly mud-supported (calcimicrobial) towards predominantly grain-supported (rudist-algal) facies types. An Early Aptian hiatus with a coeval onset but a 1 Myr longer duration has been reported from the Monte Croce section in the Aurunci Mountains (Fig. 3.10), located about 25 km southwest of Villa Santa Lucia (Di Lucia et al., 2012).

The second hiatus (3.3 Myr) appears as an exposure surface associated with incipient soil formation on top of fenestral limestones characterised by voids filled with greenish argillaceous micrite and a meteoric negative C-isotope spike (-0.2 ‰) recorded a few meters below the surface (Fig. 3.3). An abrupt decline of  $^{87}\text{Sr}/^{86}\text{Sr}$  values (from 0.707293 towards 0.707211) clearly indicates that large parts of the Late Aptian are missing in the SL sedimentary record. Several sections across the ACP (e.g. Mt Croce, Serre Sbregavitelli and Monte Tobenna/Faito; Fig. 3.10) also provide evidence for an expanded Late Aptian emersion episode (D'Argenio et al., 2004; Raspini, 2012; Ruberti et al., 2013; Buccione et al., 2016).

**Fig. 3.10:** Comparison of  $\delta^{13}\text{C}$  trends of shallow marine successions across the ACP including Monte Croce (Di Lucia et al., 2012), Serra Sbragavitelli (Ruberti et al., 2013; D'Argenio et al., 2004) and Monte Tobenna/Faito (Raspini, 2012; D'Argenio et al., 2004). Existing shallow water records were correlated to the here established chronostratigraphic framework of the MLC

and SL sections. Important bioevents used for stratigraphic correlation are marked. Note that not all bioevents are observed in all the different sections.

The youngest emersion phase (Middle Albian to uppermost Middle Cenomanian) at the SL locality is documented by a prominent 2-m-thick brick-red, karst-filling bauxite level (Fig. 3.3, 515 m) referred to as bx1 (Chiocchini et al., 2005), which is assumed to have formed from lateritic weathering of windblown volcanic ash (Bárdossy et al., 1977; Mondillo et al., 2011). This particular horizon is a well-documented feature of numerous Apennine and Apulian carbonate platform successions (Carannante et al., 2007; Mondillo et al., 2011). Considering chemostratigraphic and biostratigraphic evidence, the time lost in the bx1 level is in the order of about 14.3 Myr, a time span that is significantly longer than previously thought considering biostratigraphic data (1 to 10 Myr: Chiocchini et al., 1989; D'Argenio and Mindszenty, 1995; Chiocchini et al., 2005).

The widespread occurrence of the bx1 karst bauxite of the ACP area has been proposed to be the result of tectonically controlled exposure of vast carbonate platform areas under globally warm and humid climate conditions, combined with sufficient aeolian (volcanic) sediment supply (D'Argenio and Mindszenty, 1995). The long-lasting Cretaceous emersion phase of the ACP, which was required for bauxite formation, was probably caused by tectonic activity, induced either by (i) a lithospheric bulge during an early phase of the Alpine orogeny (D'Argenio and Mindszenty, 1995) or (ii) a Cretaceous to Cenozoic E-W oriented, left-lateral strike-slip fault (Schettino and Turco, 2011). This tectonic activity combined with the variable spatial distribution of windblown material caused the discontinuous formation of karst bauxite.

### 3.8 Conclusions

Integrated bio- and chemostratigraphy was used to establish a high-resolution chronostratigraphic age-model for the mid-Cretaceous (Barremian to Cenomanian) shallow marine successions of the Central ACP. Studied sections represent lagoonal (SL) and marginal platform settings (MLC). Both stratigraphic sections contain various exposure surfaces, which result in a fragmentary record of the successions. These exposure surfaces differ in terms of their sedimentological expression, geochemical signature and the amount of time covered by the corresponding hiatuses:

1. The SL section, ranging from the Barremian to the Cenomanian, contains three stratigraphic hiatuses. A first hiatus covers parts of the Early Aptian (~ 3.2 Myr), with a thin brecciated interval representing the hiatal surface. The second hiatus is dated to Late Aptian (~ 3.3 Myr) and associated with soil formation on top of a fenestral limestone that contains voids filled with greenish argillaceous micrite as well as a negative carbon isotope shift. The youngest hiatus ranges from Late Albian to Middle Cenomanian (~ 14.3 Myr) and is expressed in the field as a prominent 2-m-thick, red bauxite interval (bx1).

2. Similar to the SL section, the MLC section (Late Aptian to Early Albian) contains a Late Aptian hiatus (~ 3.3 Myr). In the field, this interval shows numerous cm- to dm-thick intra-formational karst-related breccia horizons (angular limestone clasts embedded in a greenish-brownish argillaceous matrix).
3. The Late Aptian hiatus is recorded in several shallow marine carbonate successions across the ACP (incl. Monte Croce, Serra Sbragavitelli, Monte Tobenna/Faito), which allows a platform-wide correlation of the sections and to integrate them into the here established stratigraphic framework.

### Acknowledgements

We thank Christiane Wenske (LUH) for laboratory assistance and Fritz-Lukas Stoeckle (LUH) for thin section preparation. Financial support from German Research Foundation (DFG) project HU 2258/2-1186 (SH) and HE 4467/8-1 is gratefully acknowledged.

## 4. Platform-wide Shift to Microbial Carbonate Production during the Late Aptian cold snap

K. SCHMITT, U. HEIMHOFER, G. FRIJIA, S. HUCK

*To be submitted to Geology.*

### Abstract

Transient episodes of microbial carbonate resurgence in the aftermaths of Phanerozoic major extinction events have been linked to the dramatic decline of grazing metazoans leaving a wide range of ecological niches. Apart from the loss of metazoan competitors, the factors causing pervasive microbial carbonate production are not completely understood. Amongst others, outstanding warm temperatures coupled with low oxygenated waters were proposed as possible triggers. This study focuses on Late Aptian shallow marine carbonates deposited on the Apennine Carbonate Platform (ACP) in the central Tethys, where a platform-wide shift from a metazoan-dominated ecosystem to microbial ‘bacinelloid’ carbonate production is reported. By establishing an integrated high-resolution chemostratigraphic framework for two sections of the ACP, a coeval onset of pervasive bacinelloid growth is discovered. This initial phase coincides with the late stage of the so-called Late Aptian “cold snap” and the subsequent temperature increase, which was paralleled by a significant sea level rise. Our results contrast with observations from the Early Aptian Oceanic Anoxic Event 1a, where a similar shift towards microbial ‘bacinelloid’ carbonate production has been linked to exceptionally warm conditions and hypoxia.

### 4.1 Introduction

Most Phanerozoic reefal and carbonate platform ecosystems were composed of both microbial and skeletal organisms in a mutually beneficial relationship (Webb, 1996). In the aftermath of major biocrises, however, biodiverse metazoan-dominated reef ecosystems were often replaced by microbial carbonate-producing communities (e.g. Pomar and Hallock, 2008). Following the end-Permian mass extinction, for instance, the delayed recovery of metazoan grazers caused widespread microbialite formation in subtidal settings (Schubert and Bottjer, 1992). This reorganization of shallow water carbonate ecosystems is seen as a biological feedback to environmental pressure caused by Siberian Traps volcanism (Pietsch and Bottjer, 2014). It seems likely that the exclusive dominance of neritic microbialite production was fostered by exceptionally high sea-surface temperatures (SSTs) in combination with low dissolved oxygen levels and probably enhanced nutrient availability (e.g. Sun et al., 2011; Kershaw et al., 2012).

A similar set of environmental stressors may have acted on marine calcifying organisms during the mid-Cretaceous emplacement of the Ontong Java Plateau large igneous province (OJP-LIP; Erba et al., 2015). Biotic feedbacks to Early Aptian OJP-LIP related environmental perturbations include a crisis amongst calcareous nannoplankton (Erba et al., 2010), the demise and drowning of subtropical carbonate platforms (Föllmi et al., 1994), the widespread accumulation of organic matter (e.g. Jenkyns, 2010) during Oceanic Anoxic Event (OAE) 1a and the coeval proliferation of *Lithocodium-Bacinella* microencrusters in Tethyan shallow water carbonate platform habitats at the expense of coral-rudist platform communities (Immenhauser et al., 2005; Huck et al., 2010). The taxonomic position of *Lithocodium aggregatum*, *Bacinella irregularis* and ‘lithocodoid’ and ‘bacinelloid’ fabrics is still under debate, but it is widely accepted that these microproblematica should be attributed to encrusting algal and calcimicrobial communities (see discussion in Huck et al., 2012).

At this stage, it remains unclear whether shallow water *Lithocodium-Bacinella* episodes were mainly driven by short-lived global warming (hyperthermal) events, probably in combination with platform hypoxia that are superimposed on the long-term Early Aptian warming trend (Huck et al., 2012; Hüter et al., 2019). Indeed, isolated *Lithocodium* and/or *Bacinella* occurrences were reported from various Late Aptian and Early-Middle Albian shallow water settings (e.g. Neuweiler and Reitner, 1992; Greselle and Pittet, 2005; Waite et al., 2007; Di Lucia et al., 2012), but these microbial episodes often lack a precise stratigraphic assignment, which would allow them to be placed into a global context of environmental change.

The current study documents multiple pulses of pervasive bacinelloid microencruster growth in two Tethyan carbonate platform sections (Apennines, Italy) during the Aptian-Albian boundary interval. The overall aim is to chemostratigraphically (C, Sr) pin-point the onset of bacinelloid mass occurrences and to capture the spatial and temporal patterns of carbonate platform ecology change. The latter will be of importance for a better understanding of the palaeoecological impact of the Late Aptian ‘cold snap’ (Mutterlose et al., 2009; McAnena et al., 2013) and OAE1b-related environmental changes on shallow water carbonate platform communities.

## 4.2 Geological setting

During the mid-Cretaceous, the Apennine Carbonate Platform (ACP; Fig. 4.1 A) was one of several isolated central Tethyan carbonate platforms bordered by the Molise-Sannio-Lagonegro basin in the North (Fig. 4.1 B) at a palaeolatitude of about 15°N. The studied 153 m-thick Santa Lucia (SL; 41°31'00.6"N 13°46'40.0"E) and 166 m-thick Monte La Costa (MLC; 41°28'12.4"N 14°29'50.0"E) shallow water successions represent back-reef and shelf-margin settings of the ACP, respectively and are largely composed of thick-bedded peloidal-bioclastic and foraminiferal grain- and rudstones with mud-supported intercalations. The typical platform biota comprises radiolitid rudists, chondrodonts, gastropods, benthic foraminifers including orbitolinids, dasycladacean algae and solitary corals. A

remarkable feature characterizing both the SL and MLC sections is the repeated pervasive growth of bacinelloid microencrusters. Biostratigraphically, the studied limestone deposits are assigned to the Aptian-Albian ‘Calcari con Requenie e Gasteropodi’ Formation’ (Di Stefano et al., 2011).

**Fig. 4.1:** (A) Palaeogeographic map of the Upper Cretaceous showing the location of the study area in the Tethys and North Atlantic deep-sea sections considered in the text (modified after Huber and Leckie, 2011). (B) Location of the studied sections (1: Santa Lucia; 2: Monte La Costa) in the Central and Southern Apennines, Italy (modified after Frijia and Parente, 2008).

### 4.3 Methods

Samples for microfacies and geochemical investigations were taken at a spacing of  $\sim 0.5$  to 1 m. Bacinelloid microencrusters were studied and semi-quantitatively analyzed in 55 petrographic thin sections. The differentiation of bacinelloid morphotypes is based on the classification scheme of Rameil et al. (2010) and Huck et al. (2012).

The most fine-grained portion of 436 bulk carbonates was sampled with a hand-held micro-drill and measured for its carbon and oxygen isotope composition at the Institute of Geology at Leibniz University Hannover (LUH), Germany. Certified carbonate standards (NBS 19, NBS-18, IAEA, CO-1) produce an external reproducibility of 0.08 ‰ for  $\delta^{18}\text{O}$  and 0.06 ‰ for  $\delta^{13}\text{C}$ . All isotope results are reported in ‰ relative to the Vienna-Pee Dee Formation belemnite (VPDB) standard in the conventional delta notation. For Sr-isotope analyses, the preservation state of outer shell layers of low-Mg calcite bivalve shells (rudists:  $n = 5$ ; chondrodonts:  $n = 3$ ) was examined by elemental compositions (Ca, Mg, Sr, Fe and Mn) provided by inductively coupled plasma-atomic emission spectrometry at the Institute of Geology, Mineralogy and Geophysics at Ruhr-University Bochum (RUB), Germany. In total, five rudist and three chondrodont shells were analyzed at RUB for  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios using a Finnigan MAT 262 thermal ionization mass-spectrometer in dynamic mode.

## 4.4 Results

Bacinelloid fabrics are characterized by differently sized and shaped sparite-filled vesicles or ‘cells’ (Schlagintweit et al., 2010) that either form (I) oncoids ( $\text{\O} 250 \mu\text{m}$  to 5 cm), (II) irregular shaped cm-sized patches or (III) massive, laminar crusts. In the inner carbonate platform domain - covered by the SL section - the dominance of bacinelloid microencrusts is demonstrated by the intermittent occurrence of m-thick beds of float- and rudstones bearing bacinelloid morphotypes I and II (Fig. 4.2: 58–75 m; 124–148 m). The size and volumetric abundance of morphotype I is strongly variable, including stratigraphic levels comprising small-sized, dispersed or cm-sized amalgamated (condensed) and partly reworked oncoids. At the platform margin represented by the MLC section, massive bacinelloid boundstone facies types in rock-forming abundance (morphotype III) occur at several stratigraphic intervals (27–74 m; 124–140 m). In contrast to the SL locality, morphotypes I and II are rare or absent.

**Fig. 4.2:** Comparative facies characteristics, lithostratigraphy and chemostratigraphy (C, Sr) of the SL and the MLC sections. Correlation of both sections (blue lines) is based on characteristic carbon isotope trends and inflexion points. Green and red bold lines represent the 5-point moving average curves. Note the coeval appearance of bacinelloid microencrusts during the Upper Aptian at both sites.

Both sections, although ~ 60 km apart, show a remarkably similar stratigraphic  $\delta^{13}\text{C}$  pattern characterized by a double-peaked positive carbon isotope excursion (CIE) reaching up to 4.5 ‰ (MLC). The CIE is followed by sinusoidal  $\delta^{13}\text{C}$  variations (amplitude of 1 ‰) that are superimposed on a gradual negative trend (Fig. 4.2). Bivalve shell calcite from selected horizons exhibits  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios ranging between 0.707194 ( $\pm 5 \cdot 10^{-6}$ ) and 0.707316 ( $\pm 5 \cdot 10^{-6}$ ) indicative of the latest Aptian-earliest Albian interval (~ 115–111 Myr; McArthur et al., 2001;). The pristine preservation state of considered bivalve shells is proven both by well-defined growth increments composed of fibrous low-Mg calcite as well as elemental characteristics such as high Sr (rudists mean: 1161 ppm; chondrodonts mean: 676 ppm) and low Mn (rudists mean: 4 ppm; chondrodonts mean: 5 ppm) and Fe (rudists mean: 1 ppm; chondrodonts mean: 3 ppm) concentrations (Supplementary Information DR1).

## 4.5 Discussion

### 4.5.1 Platform-wide expansion of microbial carbonate production

Considering the chemostratigraphic findings, a pronounced change in facies towards an overwhelming dominance of bacinelloid microencrusters starts in the upper part of the positive CIE at both sites. This facies change marks the onset of rapid alternations between pervasive bacinelloid microencruster growth and typical photozoan carbonate production. At the SL site, the initial onset and major phase of bacinelloid microencruster growth corresponds to a ~ 17 m-thick package essentially composed of morphotypes I and II. The dominance of large bacinelloid oncoids at the SL locality points to low hydrodynamic conditions coupled with reduced sedimentation rates in a lagoonal setting (Védrine et al., 2007). At the MLC site the second peak of the CIE correlates with a ~ 47 m-thick unit composed of massive bacinelloid morphotype III. The dominance of massive crusts at the platform margin provides evidence that bacinelloid microencrusters developed morphological strategies for growth under high-energy conditions. These interpretations are in line with Early Aptian *Lithocodium-Bacinella* microencruster morphotypes identified along the Arabian carbonate platform, where delicate, autochthonous morphotypes characterize calm deeper water environments and more robust or reworked forms are typically found in high-energy settings (Rameil et al., 2010). Following an initial phase of pronounced growth, the over-lying beds are characterized by more intermittent and successively declining bacinelloid occurrence at both study sites.

A platform-wide and synchronous ecosystem shift towards microbial dominance is supported by comparison with existing studies from the ACP. Di Lucia et al. (2012) document a latest Aptian interval rich in *Lithocodium-Bacinella* nodules of subtidal open lagoon facies from the Mt. Tobenna section, located 90 km south of the MLC site (Fig. 4.1 B). In the Sbregavitelli section in the vicinity of MLC (Central ACP), large reworked *Lithocodium-Bacinella* oncoids form part of Upper Aptian channel-fill deposits (Ruberti et al., 2013). In summary, the contemporaneous invasion of bacinelloid microencrusters into lagoonal as well as marginal carbonate platform settings results in a fundamental

change in shallow water platform ecology and carbonate production mode and highlights their role as ecological generalists.

#### 4.5.2 Implications for mid-Cretaceous *Lithocodium-Bacinella* mass occurrences

The new geochemical results enable the stratigraphic correlation with a well-dated pelagic reference  $\delta^{13}\text{C}$  record from the adjacent Umbria Marche Basin in central Italy (Piobbico core: Bottini et al., 2015) and show that the onset of pervasive bacinelloid microencruster growth on the ACP falls within the uppermost portion of a prolonged Late Aptian positive CIE (Fig. 4.3). Strontium isotope ratios indicate that the platform-wide ecosystem turnover slightly postdates the Late Aptian minimum of the global marine  $^{87}\text{Sr}/^{86}\text{Sr}$  composite record (McArthur et al., 2001). Considering the GTS2012 timescale (Ogg and Hinnov, 2012), the  $^{87}\text{Sr}/^{86}\text{Sr}$  minimum can be placed at  $\sim 115$  Myr (*H. jacobi* ammonite zone), stratigraphically positioned between the 113 (Jacob) and Kilian black-shale levels of the OAE1b multi-event.

The initial expansion of bacinelloid-dominated facies occurs during a phase of peculiar climatic conditions referred to as Late Aptian ‘cold snap’ (Mutterlose et al., 2009; Millán et al., 2014; Bodin et al., 2015; O’Brien et al., 2017). Evidence for global cooling during the Late Aptian is provided by the southward migration of boreal taxa (Mutterlose et al., 2009) and glendonite occurrences in high latitudes (Herrle et al., 2015; Grasby et al., 2017). Open ocean SST estimates based on  $\text{TEX}_{86}$  data from the eastern North Atlantic (DSDP Site 545) show a distinct drop from  $\sim 32^\circ\text{C}$  during the early Late Aptian (NC7B) towards  $\sim 28^\circ\text{C}$  in the latest Aptian (NC8A) (McAnena et al., 2013), compared to exceptionally warm  $\text{TEX}_{86}$ -derived SST estimates of  $\sim 34^\circ\text{C}$  prevailing during the middle Albian (O’Brien et al., 2017). In the Umbria Marche Basin (Piobbico core), the stratigraphic interval between the 113 and Kilian levels is composed of organic-poor, red-colored marlstone indicative of well-oxygenated and probably cool bottom waters (Bottini and Erba, 2018). Chemostratigraphic correlation reveals that the main phase of bacinelloid growth on the ACP took place during the final stage of the Late Aptian SST minimum and the subsequent temperature increase (Fig. 4.3). Individual black shale levels indicative of basinal anoxia and associated with short-lasting hyperthermal conditions (McAnena et al., 2013; Bottini and Erba, 2018) show no clear lithological expression in the shallow water deposits on the ACP. This clearly contrasts with Early Aptian *Lithocodium-Bacinella* episodes related to OAE1a, which were proposed to be associated with shallow water platform hypoxia during a phase of global ocean oxygen deficiency (Hüter et al., 2019).

**Fig. 4.3:** Correlation of the SL and MLC carbon isotope profiles with a well-dated pelagic composite  $\delta^{13}\text{C}$  record from the adjacent Umbria Marche Basin (Piobbico core: Bottini et al., 2015). Age assignments of the SL and MLC sections are calibrated by means of strontium isotope stratigraphy. Sea surface temperature estimates are based on  $\text{TEX}_{86}$  data (McAnena et al., 2013). The evolution of global marine  $^{87}\text{Sr}/^{86}\text{Sr}$  values (LOWESS curve) is from McArthur et al. (2001). All data are calibrated to the GTS 2012 timescale (Gradstein et al., 2012). Brown bars represent the stratigraphic positions of pelagic organic-rich levels referred to as 113 (Jacob), Kilian and Paquier episodes (Bottini et al., 2015). Lithostratigraphic log of the Piobbico core after Bottini and Erba (2018) contains black shales (black), marlstones (green), pink to reddish marlstones (red) and brown claystones (brown).

At the MLC site, deposition of the bacinelloid interval postdates an unconformity, which marks a significant Late Aptian hiatus (Graziano and Raspini, 2015). Evidence for widespread platform exposure due to a Late Aptian sea level drop of arguable glacio-eustatic nature comes from Iberia and the Arabian plate, where deep incised valley systems back-filled with locally condensed iron-rich siliciclastics (Greselle and Pittet, 2005; Maurer et al., 2013; Bover-Arnal et al., 2014). According to Maurer et al. (2013), the long-lasting Late Aptian lowstand was followed by a rapid sea level rise in the range of  $\sim 40$  m. On the Arabian plate, this subsequent sea level rise has been placed in the APT6 3<sup>rd</sup> order sequence which corresponds to the stratigraphic interval located between the 113 (Jacob) and Paquier levels (*H. jacobi* ammonite zone). These observations indicate that the onset of sedimentation at the MLC site may reflect the APT6 sea level rise with the massive bacinelloid deposits representing a transgressive facies.

In summary, pervasive bacinelloid microencruster growth on the ACP occurs during a phase of climatic transition at the end of the Late Aptian cooling. The observed connection with relatively cool conditions and well oxygenated ocean waters clearly contrasts with shallow water *Lithocodium-Bacinella* microbial episodes during OAE1a, generally considered as a phase of outstanding global warmth (Mutterlose et al., 2014; Naafs and Pancost, 2016). Transient episodes of microbial carbonate proliferation should thus not be exclusively considered as indicator of hyperthermal and hypoxic conditions in Earth history.

## Acknowledgements

We thank Christiane Wenske (LUH) for laboratory assistance and Fritz-Lukas Stoeckle (LUH) for thin section preparation. Financial support from German Research Foundation (DFG) project HU 2258/2-1 (SH) and HE 4467/8-1 (UH) is gratefully acknowledged.

## 5. Radiolitid Rudists: An Underestimated Archive for Climate Reconstruction?

K. SCHMITT, U. HEIMHOFER, M. KRUMMACKER, N.J. DE WINTER., S. HUCK

### Abstract

Rudist shells are often used for palaeoenvironmental reconstructions in the greenhouse world of the Cretaceous. Radiolitids, a family of rudists, dominated the shallow marine carbonate platforms during the mid-Cretaceous. Still, due to their very complex low-Mg calcite outer shell layer, they are often neglected for palaeoenvironmental reconstructions. The aim of this study is to use a combination of high-resolution analytical techniques, such as  $\mu$ XRF and IRMS, in order to make radiolitid shells accessible as an archive for seasonal temperature or salinity changes during the mid-Cretaceous. Four *Eoradiolitites* shells were analysed in detail: two right valves (RV), a left valve (LV) plus its articulated RV and a LV. The results show that the valves of radiolitid rudists are a suitable archive for palaeoenvironmental reconstructions.

### 5.1 Introduction

The climate of the Cretaceous is famous for its prolonged greenhouse conditions, which were only interrupted by a few short-lived but prominent cooling events (Skelton et al., 2003; Steuber et al., 2005; Bornemann et al., 2008; Mutterlose et al., 2009). Cretaceous palaeoclimate is often reconstructed by  $\delta^{18}\text{O}$  data derived from belemnites (e.g. Bodin et al., 2015), planktonic foraminifera (e.g. Bottini et al., 2015) and TEX<sub>86</sub> (e.g. O'Brien et al., 2017). As all of them or their respective organisms are floating or migrating through the water, their isotope record contains temperatures of several habitat changes (e.g. Eggins et al., 2003). In order to avoid this open marine temperature signal, sessile organisms are favoured for analyses.

In the Cretaceous, sessile rudist bivalves dominated shallow marine, low latitude carbonate platform settings in the Tethyan Ocean and are therefore suitable for paleoenvironmental reconstruction (Ross and Skelton, 1993; Scott et al., 1995; Skelton and Gili, 2012; Steuber and Schlüter, 2012). After their first appearance in the Oxfordian (Late Jurassic) (Skelton, 1978), they evolved to the most important carbonate-producing biota (Steuber and Veizer, 2002) until they went extinct at the Cretaceous/Paleogene boundary (Skelton et al., 2003). Although various forms had evolved over time, all species can be assigned to one of three morphotypes (recumbents, clingers or elevators), which were identified in previous taxonomic studies (Schumann and Steuber, 1997; Skelton and Gili, 1991).

However, all species built shells following a similar basic shell design: An outer layer composed of fibrous prismatic low-Mg calcite and (two) inner aragonitic layers (Kennedy and Taylor 1968;

Skelton 1974; Sanders, 1999; Pons and Vicens, 2008). The aragonitic layers are usually replaced by diagenetic low-Mg calcite during fossilization, but the outer low-Mg calcite layer provides material with a high potential to act as an archive for seawater chemistry, as it is resistant to diagenesis (Al-Aasm and Veizer 1986 a, b). For instance, previous studies have shown that the outer low-Mg calcite layer of Cretaceous rudist shells is a precious archive for the strontium isotope composition of ocean waters (Steuber et al., 2005; Frijia and Parente, 2008; Frijia et al., 2015; Huck and Heimhofer, 2015). Additionally, it is suitable as palaeoenvironmental archive as the secretive processes of the shells were affected by palaeoclimatic (seasonal temperature variations), palaeochemical (salinity changes) and palaeobiological (growth rate and carbonate production) parameters (e.g. Steuber 1996; Regidor-Higuera et al., 2007; de Winter et al., 2017a).

Rudists have proven to be very suitable for climate reconstruction in the Lower Cretaceous (Steuber et al., 2005) but during the mid-Cretaceous the climate record is incomplete as the suitable material is missing. This is partly due to the fact that radiolitids, a family often overlooked as a palaeoclimate archive, became dominant during the middle Aptian (Masse and Gallo Maresca, 1997; Fenerci-Masse et al., 2006; Skelton and Gili, 2012). The taxonomy of the shells of radiolitids was discussed and defined in various previous studies (Pons and Vicens, 2008; Cestari, 1992; Schumann, 1995; Skelton, 1978): In general, the right attached valve (RV) of radiolitids is described as conical to cylindro-conical, while the left free valve (LV) is reduced to a cap-like form with a compact structure (Pons and Vicens, 2008). The most significant feature of radiolitid shells is the special structure in their outer layer of the RV, where compact and non-compact structures are alternating. The non-compact portion is often distinct as honeycomb (Woo et al., 1993; Steuber, 1999), boxwork (Hamama, 2010), cellular (Masse and Maresca, 1997; Masse et al., 2007) or celluloprismatic structure (Pons and Vicens, 2008). It is formed by two kinds of laminae (or plates): the funnel plates and the radial plates (muri or walls). The latter is arranged orthogonal to the funnel plates (Masse et al., 2007; Fig. 5.1) creating an intraskeletal pore space, which was probably originally filled with organic material (Regidor Higuera et al, 2007). This material decomposed after death and was filled post-mortem with diagenetic low-Mg calcite cement (Tibljaš et al., 2004; Mansour, 2004). For a more detailed description of the radiolitid shell structure, please refer to Regidor-Higuera et al. (2007).

**Fig. 5.1:** Schematic construction of a radiolitic shell showing the cone shaped lower (right) valve with detailed view of the boxwork structure and the cap like upper (left) valve (modified after Sanders, 1999 and Pons and Vicens, 2008).

Only few studies deal with the elemental and isotopic composition of radiolitic shells (Steuber, 1999; Regidor-Higuera et al., 2007; Tibljaš et al., 2004). They suggest that radiolitics are not suitable for palaeoenvironmental reconstructions, as their porous outer shell layer allows fluids to circulate through the pores causing diagenetic alteration. Additionally, sampling for unaltered material is difficult due to the alternation of compact and non-compact parts. The aim of this study is twofold:

- (I) Firstly, high-resolution geochemical analyses (isotope ratio mass spectrometry and micro-X-ray fluorescence) and classical sclerochronology (macro and microstructures) are combined to identify diagenetically altered parts.
- (II) Secondly, the suitability of radiolitic shells as palaeoenvironmental archive (palaeotemperature, palaeosalinity, living habitat) is tested.

## 5.2 Material

Radiolitic rudists evolved and spread during the late Aptian-Albian to become the most diverse family among the rudists (Masse et al., 2007; Steuber and Löser, 2000). The outer shell layer of radiolitics contains micro- and megarhythms, which are caused by tidal or biological cycles (Sanders, 1999; Pons and Vicens, 2008). Megarhythms (annual cycles) are defined as major variations in the shells' ornamentation, visible in thin sections due to the change in the microstructure or in variations in the stable oxygen isotope record. Schumann (1995) proposed that a complete annual cycle includes 24-25 growth lamellae. Each growth lamella is designated as a microrhythm that is expressed as a change in colour (light and dark). They can be distinguished by width, stacking and structure. Notably, Regidor-

Higuera et al. (2007) state that the number of lamellae per year can vary between different genera and species, depending on the environment of the shell.

For this study, several radiolitid shells were collected from a shallow marine marginal carbonate platform setting in the central Tethys, today outcropping in the east-west oriented Matese Mountain Massif in southern Italy (Monte La Costa section; Fig. 5.2). Based on an integrated bio- and chemostratigraphic approach, the corresponding stratigraphic interval is dated to an Early Albian age (~112 Ma). Collected shells were screened with a magnifying glass to identify specimens that showed best preserved visible growth lamellae and low bioerosion. Finally, four very well preserved *Eoradiolitites* shell fragments (A – D) were selected from a 31 m-thick stratigraphic interval, with shell B and D originating from the same interval (MLC 387 m), followed by fragment A (MLC 401 m) and shell C (MLC 418 m). Fragments A, B and the lower part of fragment C represent different ontogenetic stages of a right valve (RV), while the upper part of fragment C and fragment D represent different portions of a left valve (LV). For further information about the lithostratigraphy and the dating, please refer to Schmitt et al. (in preparation).

**Fig. 5.2:** A. Palaeogeographic map of the Upper Cretaceous with the studied area of the Apennine Carbonate Platform in the Tethyan realm. B. Study site in the Matese Mountains, Italy.

Radial cuts, perpendicular to the growth laminae, of representative shells were used to prepare thin sections and slabs, which allow to identify changes in the microstructure and to assess sclerochronological changes in isotopic and elemental compositions, respectively. The length of RV fragments varies from 27.6 mm (shell B) to 52.5 mm (shell A). The LV (shell D) fragment is 59.5 mm in diameter. Shell C consists of an articulated LV (13 mm) and RV (26.2 mm). The inner aragonitic layer (al), the inner part of the outer layer (il), the outer layer (bl) and borings were identified in all shell parts (Fig. 5.2). Detected mineral fractions are micrite and sparite. The former aragonitic parts are

recrystallized and preserved as blocky diagenetic low-Mg calcite and are thus excluded from further analyses.

### 5.3 Methods

Selected valves were cut along their perpendicular axis, cleaned with distilled water and dried for 24 h at 40 °C. Afterwards, thin sections and polished slabs were prepared (Fig. 5.3).

**Fig. 5.3:** Schematic representation of a radiolitid shell with the selected shells of this study. (A) Right valve; (B) Right valve; (C) Articulated right and left valve; (D) Left valve.

The preservation state of collected shell samples was tested using cathodoluminescence (CL) microscopy. CL was applied to thin sections and slabs using a Reliontron (Relion, U.S.A) cold-cathode luminescence device hosted at the University of Texas at San Antonio (USA). The CL microscope is characterized by an acceleration voltage ranging from 10 to 15 kV and a current intensity ranging from 0.8 to 1.2 mA. The CL chamber was mounted on a Leica DM2700 microscope equipped with 2.5x, 4x, 10x and 20x magnification objectives.

Following petrographic inspections, the elemental composition of shells representing different ontogenetic stages of the animal were measured by means of a Tornado M4 micro X-ray fluorescence ( $\mu$ XRF) scanner (Bruker nano GmbH, Berlin, Germany), hosted at the Analytical, Environmental and Geochemistry research group of the Vrije Universiteit (Brussel). The  $\mu$ XRF scanner is equipped with a Rh source and two X Flash 430 Silicon Drift detectors. First, semi-quantitative  $\mu$ XRF-maps were created in order to assess the distribution of major and trace elements across the surface of shell fragments. Polished shell surfaces were scanned in the  $\mu$ XRF mapping mode using a short acquisition time of 1 ms per pixel. Maps were created by focusing the X-ray beam on a circular spot with a diameter of 25  $\mu$ m and dragging the beam across the polished surface, collecting  $\mu$ XRF spectra every 50  $\mu$ m in X and Y direction. This procedure yielded  $\sim 10^6$   $\mu$ XRF spectra per sample, which allowed semi-quantitative maps

of elemental distribution to be created based on differences in the area of peaks in the  $\mu$ XRF spectrum associated with elements (ROI counts; see de Winter and Claeys, 2016). This mapping procedure allowed maps of a range of elements to be created, a selection of which is used in this study (magnesium, manganese, iron and strontium).  $\mu$ XRF mapping together with CL was used to check the preservation of the samples and to guide sampling for further analyses.

Quantitative point-by-point  $\mu$ XRF line scans were performed perpendicular to growth lamellae along the maximum growth axis of each shell fragment with a sampling resolution of 100  $\mu$ m. Point-by-point line scans allow the X-ray beam to remain on each point for 60 s at maximized energy settings (50 kV, 600  $\mu$ A, no source filter). This time of analysis represents the ideal compromise between lowering the signal-to-noise ratio (by increasing measurement time) and increasing the spatial sampling resolution (by increasing the amount of measurements). This causes the signal-to-noise ratio of individual spectra to be high enough to allow quantification of individual spectra to produce accurate and reproducible measurements of concentrations of a range of major and trace elements (see discussion in de Winter et al., 2017b). Therefore, XRF spectra in line scans yield quantitative major and trace element profiles, contrary to spectra of pixels in XRF maps, which can only be used to measure relative changes in element abundances. While concentrations of many elements could be quantified in line scans, only concentrations of strontium (Sr), manganese (Mn), magnesium (Mg) and iron (Fe) are used in this study.

For stable isotope analysis, shells were sampled perpendicular to visible growth lamellae on a sub-millimetre scale. The length of shell transects ranges from 27.6 to 59.5 mm. Carbonate powders ( $\sim$  150-200  $\mu$ g) were extracted using a ESI New Wave micromill equipped with a Brassler® USA scriber point carbide drill bit ( $\varnothing$  0.08 mm). The spacing between the samples was  $<0.1$  mm. A total of 432 samples (A: n=105; B: n=80; C: n=39; D: n=208) were analysed in the stable isotope laboratory of the Institute for Geology, Leibniz University Hannover, Germany using a Thermo Fisher Scientific Gasbench II carbonate device connected to a Thermo Fisher Scientific Delta 5 Advantage isotope ratio mass spectrometer. One hour before the measurements were started, 72°C hot viscous water-free (98 g mol<sup>-1</sup>) orthophosphoric acid was added to the sample powders, resulting in the release of CO<sub>2</sub>. Repeated analyses of certified carbonate standards (NBS 19, IAEA 603, NBS 18 and Carrara Marble) show an external reproducibility of  $\leq 0.06$  ‰ for  $\delta^{13}\text{C}$  and 0.08 ‰ for  $\delta^{18}\text{O}$ . Isotope ratios are reported as conventional delta values relative to the Vienna-Pee Dee Formation belemnite (VPDB) international standard, in parts per thousand (‰).

Sea surface temperatures (SST) were calculated using the equation of Anderson and Arthur (1983):

$$T [^{\circ}\text{C}] = 16 - 4.14 * (\delta^{18}\text{O}_{\text{CaCO}_3} - \delta^{18}\text{O}_{\text{H}_2\text{O}(\text{seawater})}) + 0.13 * (\delta^{18}\text{O}_{\text{CaCO}_3} - \delta^{18}\text{O}_{\text{H}_2\text{O}(\text{seawater})})^2$$

with an estimated  $\delta^{18}\text{O}_{\text{H}_2\text{O}(\text{seawater})}$  of -1 ‰ for the Tethys ocean under ice-free conditions in the Barremian to Campanian (Friedrich et al., 2012; Anderson and Arthur, 1983; Shackelton and Kennett, 1975; Steuber, 1996; Steuber and Rauch, 2005).

## 5.4 Results

### 5.4.1 Shell micro- and macrostructures (sclerochronology *sensu stricto*)

On a macroscopic scale, all analysed shell fragments exhibit clearly distinguishable growth lamellae as well as colour variations (transparent to dark brown) (Fig. 5.4 to 5.7). An exception is the RV shell fragment C, whose sparite-filled, celluloprismatic structure produces a significantly lighter colour (Fig. 5.6; A). Due to their different shell structure, all shells were assigned to three categories: (I) non-compact (RV: shell A and B), (II) compact (LV: shell D and C) and (III) celluloprismatic (RV: shell C).

In general, whitish to transparent parts of analysed outer shell layers match the areas of the corresponding thin sections where growth lamellae are non-compact, which is expressed in shell A and B as blurry, incomplete, sinuous and/or not distinguished appearance (dashed lines in Fig. 5.4 to 5.7). In the non-compact parts, the width of the alternating dark and light growth lamellae is highly variable (their stacking is uneven). Darker coloured shell parts correspond to the areas of the shell with a compact fibrous microstructure. Here, cyclic alternations of distinct light and dark, densely packed growth lamellae with an even stacking, are visible (solid lines in Fig. 5.4 to 5.7). The RV of shell C shows the classical celluloprismatic structure described in Pons and Vicens (2008). All shell fragments contain borings and/or cracks that interrupt or destroy the growth lamellae.

The flame-like shaped growth rings (concentric rugae), i.e. arranged lamellae sets, are visible on a macroscopic scale (Fig. 5.2; Fig. 5.5 F). On a microscopic scale, they can be seen due to changes in the inclination of the growth lamellae (Fig. 5.4 G). A detailed analysis of thin sections revealed that a downwards concentric fold is visible in all RVs, surrounding the recrystallized inner part of the outer layer (il; see Fig. 5.4 F; 5.5 E; 5.6 E).

In total, shell fragment A comprises 144 growth lamellae. Only the outermost margin of the lip is formed by a compact fibrous microstructure (Fig. 5.4 G). Most parts of the shell are characterized by non-compact growth lamellae (Fig. 5.4 E).

**Fig. 5.4:** Shell A: (A) Image of the slab with areas shown in detailed photomicrographs marked as black boxes. (B) Schematic sketch of the most important features of the shell. (C) Thin section (ppl) with non-compact (dashed line) and compact parts (solid line). (D) Steeply inclined growth lamellae. (E) Non-compact growth lamellae. (F) Detailed view (plane-polarized light) showing the transition from il (concentric fold) to bl (outer boxwork layer). (G) The thickness and expression of single growth lamellae is highly variable.

Shell fragment B contains 54 growth lamellae characterized by variable development and stacking pattern (Fig. 5.5 G). The shell exhibits compact structured parts with very prominent, steeply inclined growth lamellae (Fig. 5.5 E) alternating with non-compact parts, containing a non-distinguishable structure. The outer part of the flame-like shape of the growth rings is often surrounded by a micritic seam. One prominent micrite filled boring trace occurs in the ontogenetically oldest part of the shell (Fig. 5.5 D).

**Fig. 5.5:** Shell B: (A) Image of the slab with areas shown in detailed photomicrographs marked as black boxes. (B) Schematic sketch and the most important features of the shell. (C) Thin section (ppl) with non-compact (dashed line) and compact parts (solid line). (D) Boring filled with micritic calcite. (E) Steeply inclined growth lamellae. (F) Flame-like shape of growth rings on a macroscopic scale. (G) Variation of expression and the stacking of the growth lamellae.

Shell C comprises 130 growth lamellae (LV: n=22; RV: n=108). The right valve shows a predominant regular alternation of growth lamellae and voids, creating a roughly regular radial pattern, which is classified as ‘compact with radial elongated voids’, following Pons and Vicens (2008) (Fig. 5.6 G). All cells are filled with blocky calcite. The bl disintegrates at the outer margin of the lip into single cells. At the transition from the LV to the RV the radial furrow is preserved (Fig. 5.6 F). The LV features a small protrusion composed of the massive calcite layer (mc) and the former aragonitic layer (al), which matches the il and the calcite lamellae (cl) of the RV. Compact lamellae of the left valve are parallel near the il but incline softly towards the margin (Fig. 5.6 E).

**Fig. 5.6:** Shell C: (A) Image of the slab with areas shown in detailed photomicrographs marked as black boxes. (B) Schematic sketch and the most important features of the shell. (C) Thin section (ppl) with celluloprismatic structured (cross-hatched double line) and compact parts (solid line). (D) transition of LV(compact) and RV (celluloprismatic structure). (E) compact

structure of the LV. (F) Transition from the RV to the LV with furrow. (G) Detailed view of the celluloprismatic structure of the bl.

In total, 238 equally distributed growth lamellae were counted in shell D (Fig 5.7 G). Occasionally, particularly pronounced growth lamellae appear (Fig. 5.7 H), which differ from the others due to their very dark colour and higher diameter. Most parts of the shell show a fibrous prismatic structure. Special features of the shell represent borings that are refilled with fine grained micritic calcite (Fig. 5.7 E). At some parts the shell margin is micritized.

**Fig. 5.7:** Shell D: (A) Image of the slab with areas shown in detailed photomicrographs marked as black boxes. (B) Schematic

sketch and the most important features of the shell. (C) Thin section (plane-polarized light) with blurry (dashed line) and compact parts (solid line). (D) Lowermost part of the ligament. (E) Boring. (F) Middle part of the ligament. (G) Continuous stacking. (H) Particularly pronounced growth lamellae. (I) Changed inclination of the growth lamellae caused by a crack.

All sclerochronological and sclerochemical results are summarized in Tab. 5.1.

**Tab. 5.1:** Identified  $\delta^{18}\text{O}$  cycles, number of growth lamellae per cycle, distance describes the measured length of the cycles, calculated growth per year (mm) and mean growth lamellae diameter per cycle. Measured maximum and minimum values of  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  values and their calculated median.  $T(^{\circ}\text{C})$  was calculated for all  $\delta^{18}\text{O}$  values.

### 5.4.2 Elemental and isotope compositions

CL was applied to compact, non-compact and celluloprismatic shell structures (Fig. 5.8 A – F). Compact shell portions show a dim, orange luminescence between single growth lamellae. Growth lamellae themselves are non-luminescent. Within single cells of non-compact structures (celluloprismatic), dark brown to light orange CL colours provide evidence for various cement generations (Fig. 5.8 E and F).  $\mu$ XRF element mapping provides valuable information with respect to the preservation state of considered shells. Inclusions with higher concentrations of Fe and Mn indicate recrystallized or bioeroded parts (borings) of the shells. The light blue to green coloured parts of the shells are associated with higher Sr concentrations than the surrounding matrix (Fig. 5.8 G – J).

**Fig. 5.8:** (A) Slab of a compact shell part. (B) and (C) Thin sections of non-compact parts under ppl. (D) and (E) Compact parts are quenching CL (caused by  $\text{Fe}^{2+}$ ), while fine fractures and the non-compact parts are enriched in  $\text{Mn}^{2+}$ , which enhances CL. (G) to (J) strontium variations in the  $\mu$ XRF maps. Especially in shells B (H), C (I) and D (J) the variability in Sr between shell structures is clearly visible. At shell C (H) and D (J) the cap (LV) is displayed. In the scans of A (G) and B (H), on the other hand, single micro and macro structures cannot be distinguished.

Due to the high-resolution and the extensive dataset on a  $\mu\text{m}$  scale of the  $\mu$ XRF line scans, the data were filtered to eliminate analytical outliers. Their occurrence was linked to irregularities, such as boreholes or cracks in the shell. In addition, thresholds were defined following Steuber (1999) and cross-

plots were used to delimit clustering data points from outliers (Fig. 5.9). All Sr values below 900  $\mu\text{g/g}$  and above 1500  $\mu\text{g/g}$ , all Mn values  $> 200 \mu\text{g/g}$  and all Fe values  $> 300 \mu\text{g/g}$  were excluded from further analysis. Finally, 10pt-averages were calculated. Raw data and selected values are summarized in Tab. 5.2.

**Fig. 5.9:** Fe vs Mg and Mn vs. Sr of the here analysed shells. Due to their clustering thresholds were assumed: Sr 900-1500  $\mu\text{g/g}$ , Fe:  $< 300 \mu\text{g/g}$ , Mn  $< 200 \mu\text{g/g}$  for further analysis. For Mg, no threshold was applied as the data points scatter widely.

**Tab. 5.2:** Elemental compositions ( $\mu\text{g/g}$ ) of selected low-Mg carbonate rudist shells of the Monte La Costa section before (a) and after (b) the thresholds were applied. Data provided in (b) are the basis for further analysis.

Sample no	Sr ( $\mu\text{g/g}$ )			Fe ( $\mu\text{g/g}$ )			Mn ( $\mu\text{g/g}$ )			Mg ( $\mu\text{g/g}$ )			
	Min.	Max.	Mean	Min.	Max.	Mean	Min.	Max.	Mean	Min.	Max.	Mean

	D	1118	1495	1313	25	274	92	0	186	49	1074	2300	1459

Oxygen isotope values of shell A (Fig. 5.10) vary between -2.8 ‰ and -4.23 ‰ (mean: -3.66 ‰; s.d.: 0.33 ‰), whereas carbon isotope values range from 1.80 ‰ to 3.44 ‰ (mean: 2.32 ‰; s.d.: 0.31 ‰). In total, five  $\delta^{18}\text{O}$  cycles with amplitudes of < 1 ‰ were identified, showing either a periodic triangular or a saw tooth shape (Fig. 5.10). Most  $\delta^{13}\text{C}$  values oscillate around a value of 1.20 ‰. Superimposed rapid changes in  $\delta^{13}\text{C}$  towards more positive values weakly correlate with corresponding positive shifts in  $\delta^{18}\text{O}$  (Fig.5.6: 1.8-3.8 cm:  $r^2=0.2$ ).  $\mu\text{XRF}$  line scanning provides evidence for periodic changes in Mg concentrations (period: 0.3-0.6 cm), ranging from 1669 to 3500  $\mu\text{g/g}$ . An exception from this pattern is a prominent positive spike reaching Mg concentrations of 4923  $\mu\text{g/g}$  (Fig. 5: 2.1 cm). Sr concentrations fluctuate between 933  $\mu\text{g/g}$  and 1102  $\mu\text{g/g}$ . Significantly higher amounts of Sr (< 1350  $\mu\text{g/g}$ ) are recorded in the lower third of the shell (Fig. 5.10: 1.3 to 1.8 cm). Fe concentrations are highly variable (37  $\mu\text{g/g}$  to 191  $\mu\text{g/g}$ ), with values oscillating around a mean value of about 92  $\mu\text{g/g}$ . Mn concentrations range from 0  $\mu\text{g/g}$  to 156  $\mu\text{g/g}$ , exhibiting a superimposed cyclic pattern with higher frequency in the upper part of the shell (Fig.5.6: 3-4.2 cm).

**Fig. 5.10:** Oxygen and carbon isotopic composition with Sr, Fe, Mn and Mg variations plotted against the identified and counted growth lamellae of shell A. Dashed lines show the non-compact shell structure parts, solid lines show compact parts.

Oxygen isotope values of shell B (Fig. 5.11) vary between -2.91 ‰ and -4.35 ‰ (mean: -3.59 ‰; s.d.: 0.36 ‰), whereas carbon isotope values range from 0.93 ‰ to 2.48 ‰ (mean: 1.82 ‰; s.d.: 0.30 ‰). Identified  $\delta^{18}\text{O}$  cycles ( $n=2$ ) exhibit a triangular to sinusoidal shape with a mean amplitude of 1.3 ‰ and a wavelength of 0.7 cm and 1.4 cm, respectively (Fig. 5.11). Gradually decreasing values

characterizing the second cycle are likely explained by a slightly oblique cut through growth lamellae. Carbon isotopes lack a similar cyclic pattern and fluctuate around a background value of about 1.6 ‰. In the lower part of the shell (Fig.5.11: 0.3-1.2 cm), however, rapid negative and positive shifts in  $\delta^{13}\text{C}$  correlate well with corresponding shifts in  $\delta^{18}\text{O}$  ( $r^2=0.4$ ). Mg concentrations are characterized by periodic fluctuations (wavelength: 0.2-0.5 cm; amplitude: 1000  $\mu\text{g/g}$  to 2000  $\mu\text{g/g}$ ) that are superimposed on a cyclic sinusoidal pattern with a range from 1004 to 3520  $\mu\text{g/g}$ . Sr concentrations range from 924  $\mu\text{g/g}$  to 1435  $\mu\text{g/g}$  (median: 1239  $\mu\text{g/g}$ ) and provide evidence for a cyclic pattern. Fe concentrations exhibit a short term cyclicity (132  $\mu\text{g/g}$  to 267  $\mu\text{g/g}$ ), with values oscillating around a median value of 199  $\mu\text{g/g}$ . Mn concentrations show a cyclicity (5  $\mu\text{g/g}$  to 111  $\mu\text{g/g}$ ), with values oscillating around 45  $\mu\text{g/g}$ .

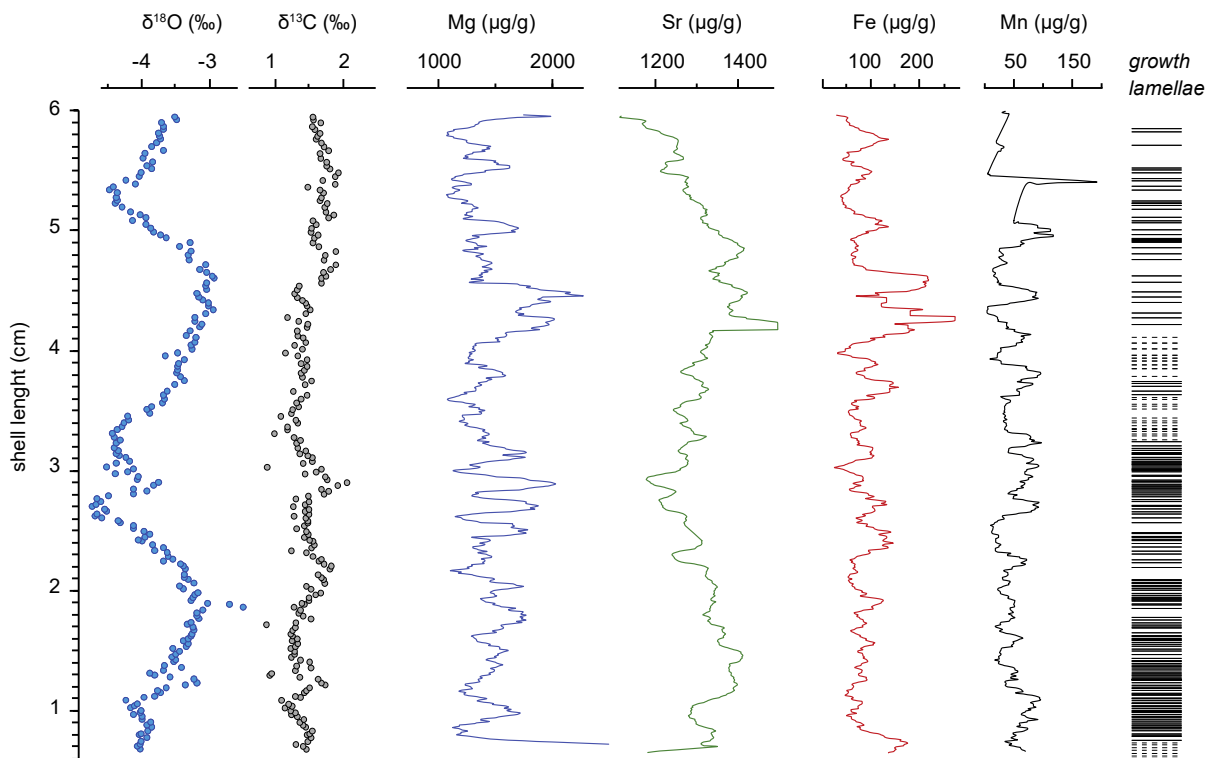

**Fig. 5.11:** Oxygen and carbon isotopic composition with Sr, Fe, Mn and Mg variations plotted against the identified and counted growth lamellae of shell B. Dashed lines show the non-compact shell structure parts, solid lines show compact parts.

Oxygen isotope values of shell C (Fig. 5.12) vary between -1.44 ‰ and -4.88 ‰ (mean: -3.51 ‰; s.d.: 0.81 ‰), whereas carbon isotope values range from 1.93 ‰ to 2.88 ‰ (mean: 2.41 ‰; s.d.: 0.23 ‰). In total, the values derived from the RV are highly variable, while the values of the LV show one broadly symmetrical sinusoidal  $\delta^{18}\text{O}$  cycle with an amplitude of <1.3 ‰ (Fig. 5.12). The  $\delta^{13}\text{C}$  values of the RV oscillate within a range between 1.9 to 2.4 ‰. A pattern is not notable. The  $\delta^{13}\text{C}$  values of the LV oscillate within a range between 2.2 to 2.7 ‰.  $\mu\text{XRF}$  line scanning of the RV shows a highly variable record with oscillations of  $\sim 500$   $\mu\text{g/g}$ , while the LV provides evidence for periodic changes in Mg concentrations (wavelength: 0.2-0.4 cm), the latter ranging from 1661 to 4588  $\mu\text{g/g}$ . The Sr concentrations of the RV fluctuate between 161  $\mu\text{g/g}$  and 264  $\mu\text{g/g}$ . The LV contains significantly higher amounts of Sr (range: 919-1428  $\mu\text{g/g}$ ) with cyclic oscillations (0.4 cm wavelength) (Fig. 5.12). Fe concentrations provide evidence for a small scale cyclicity (75  $\mu\text{g/g}$  to 247  $\mu\text{g/g}$ ), with values oscillating around a mean value of about 145  $\mu\text{g/g}$ . Significant differences between the valves cannot be observed. Mn concentrations range from 0  $\mu\text{g/g}$  to 110  $\mu\text{g/g}$ , exhibiting a superimposed cyclic pattern with wavelengths oscillating around 0.3 cm (Fig.5.12).

**Fig. 5.12:** Oxygen and carbon isotopic composition with Sr, Fe, Mn and Mg variations plotted against the identified and counted growth lamellae of shell C. Dashed lines show the non-compact shell structure parts, solid lines show compact parts.

Oxygen isotope values of shell D (Fig. 5.13) vary between -2.52 ‰ and -4.74 ‰ (mean: -3.74 ‰; s.d.: 0.47 ‰). Carbon isotope values range from 0.89 ‰ to 2.05 ‰ (mean: 1.48 ‰; s.d.: 0.20 ‰). In total, two prominent  $\delta^{18}\text{O}$  cycles with amplitudes of <1.7 ‰ were identified, showing a broadly symmetrical sinusoidal pattern (Fig. 5.13). Most  $\delta^{13}\text{C}$  values oscillate around 1.5 ‰. Superimposed rapid changes in  $\delta^{13}\text{C}$  towards more positive values correlate strongly with corresponding positive shifts in  $\delta^{18}\text{O}$  (Fig.5.9: 1.1-1.4 cm:  $R^2=0.6$  and 2.8-3.1 cm:  $R^2=0.8$ ). Mg concentrations are highly variable (1074 to 2300  $\mu\text{g/g}$ ). Sr concentrations are positively correlated with  $\delta^{18}\text{O}$  values, expressed by two symmetrical sinusoidal cycles. Concentrations range from 1118  $\mu\text{g/g}$  to 1495  $\mu\text{g/g}$ . Fe concentrations show small scale cyclic changes, with values varying from around 25  $\mu\text{g/g}$  to 274  $\mu\text{g/g}$  (mean: 92  $\mu\text{g/g}$ ). Mn concentrations show a highly fluctuating record with a range from 0  $\mu\text{g/g}$  to 186  $\mu\text{g/g}$ .

**Fig. 5.13:** Oxygen and carbon isotopic composition with Sr, Fe, Mn and Mg variations plotted against the identified and counted

growth lamellae of shell D. Dashed lines show the non-compact shell structure parts, solid lines show compact parts.

## 5.5 Discussion

### 5.5.1 Preservation state

To analyse the preservation state of the shells, the elemental and isotopic datasets were studied individually for diagenetic alteration. In elemental data, diagenesis is characterised by an increase in Mn and Fe concentrations and a decrease in the Mg and Sr concentrations (Steuber, 1999). Additionally, the correlation factor ( $R^2$ ) of isotopic values was calculated to indicate diagenetic alteration (Steuber, 1999).

#### 5.5.1.1 Elemental dataset

A cross-plot of Sr and Mg concentrations reveals that the majority of data points from shell A and D as well as samples extracted from the LV of shell C and B cluster around or close to the regression line of recent biotic calcite (blue ellipse, Fig. 5.14). Similar results were previously obtained from well-preserved *Gorjanovicia* cf. *costata* (Steuber, 1999) and *Praeradiolites ciryi* shells (Regidor-Higuera et al., 2007). As expected, the celluloprismatic RV of shell C provides Sr and Mg concentrations that plot along the abiotic calcite line (grey ellipse, Fig. 5.14). Comparable diagenetic values were reported by Tibljaš et al. (2004) for various radiolitid shells. Fe and Mn concentrations are within the range of those described in Steuber (1999) and Regidor-Higuera et al. (2007). Compared to the Mn concentrations of Tibljaš et al. (2004), the measured values are significantly higher.

**Fig. 5.14:** Mg and Sr compositions of rudist shell A (purple), B (green), C (white) and D (red) compared with mean compositions of recent biotic (upper solid line) and abiotic (lower solid line) marine calcite (Carpenter and Lohmann 1992;

Steuber 1999). Dashed lines show Sr thresholds after Steuber (1999). Also shown: radiolitids from Croatia (Tibljajš et al., 2004), Greece, United Arab Emirates (Steuber, 1999) and Spain (Regidor-Higuera et al., 2007).

The variable microstructure characterizing the outer low-Mg calcite shell layer of radiolitid rudists is expected to cause locally different elemental concentrations. The shells with a non-compact structure (Fig. F. 5.10 and Fig. 5.11) show a negative covariation between Sr and Mg. Both elements are linked to variations in metabolic activity (Rosenberg and Hughes, 1991, Klein et al., 1996) and kinetic fractionation (Carpenter and Lohmann, 1992). For this reason, it seems plausible to assume that these variations were caused by the aforementioned and not by diagenetic alteration. The compact structure of shells D (Fig. 5.13) shows a covariance of the Sr concentrations with  $\delta^{18}\text{O}$ . To explain this covariance is beyond the scope of this work. The celluloprismatic structure of the RV of shell C is considered to provide diagenetically altered results, which can be detected in low Mg and Sr but high Mn and Fe concentrations (Al-Aasm and Veizer, 1986; Steuber, 1999; Tibljajš et al., 2004). It is assumed that this is caused by the filling of the former hollow cells with secondary cement (Regidor-Higuera et al., 2007). However, diagenetic alteration can only be partially confirmed using this elemental dataset. On the one hand, very low Sr concentrations ( $< 200 \mu\text{g/g}$ ) attest to diagenetic alteration, but on the other hand, the highest measured Mg values of this complete study (3500-4000  $\mu\text{g/g}$ ) are not easily explained by diagenesis as diagenetic altered calcite should contain less Mg (Al-Aasm and Veizer, 1986; Steuber, 1999; Tibljajš et al., 2004). Additionally, the Fe and Mn concentrations are in the range of the other here analysed shells (Fig. 5.12).

### 5.5.1.2 Isotopic dataset

The variation in the  $\delta^{18}\text{O}$  pattern seems to be related to microstructural changes in the shell: Non-compact parts, described in shell A (Fig. 5.10) and B (Fig. 5.11), RVs, generate sharp shifts to positive values in the  $\delta^{18}\text{O}$  records. These sharp shifts might be the result of growth cessations caused by e.g. periods of reproduction, competition for space or critical water temperatures or salinities exceeding ecological tolerance levels (Steuber, 1996; Regidor-Higuera et al., 2007). However, the non-compact shell structure, found in shell A and B, does not automatically indicate diagenetic altered values, as no/low correlations and similar range of the  $\delta^{18}\text{O}$  values demonstrate unambiguously. A compact structure provides oxygen isotope values within an almost stable/constant range with a gradually, smooth sine function pattern, as visible in the shell D (Fig. 5.13) and C (Fig. 5.12), both LVs. This pattern of the LVs, indicates the record of seasonal changes, without any significant growth cessations. The celluloprismatic structure of the RV of shell C contains a highly variable  $\delta^{18}\text{O}$  pattern, lacking a cyclic variation. Seasonality cycles are not identifiable due to the celluloprismatic structure filled with sparite.

Although individual sclerochronological patterns are variable, all shells provide an almost identical range of  $\delta^{18}\text{O}$  values (Tab. 5.1: median range -3.31 ‰ to -4.03 ‰). Observed cyclic variations

of  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  in shell A contain a covariance, which is slightly out of phase. This is not necessarily a sign for diagenetic alteration, especially as the applied cross-plots show no (A, D), very low (B) and low correlations (C) (Fig. 5.15). These  $\delta^{13}\text{C}$  variations are supposedly due to recorded seasonal variations in marine productivity and its effect on marine dissolved bicarbonate (Arthur et al., 1983; Steuber, 1996).

**Fig. 5.15:** Cross-plot of  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  of the studied shells and their correlation factor ( $R^2$ ).

### 5.5.2 Growth variations

Annual cycles can be determined through growth rings on a macroscopic scale (shell B), through a change in shell structure on a microscopic scale (shell A) or through variations in the isotopic pattern (shell D). The relatively fragile, flame-like structure of the growth rings is often absent due to the reworking of shell fragments in high-energy marginal settings. The microscopic attempt to identify annual growth cycles is difficult due to the lack of structural changes in the growth lamellae. Therefore, isotopic values, to be more precise the values between two  $\delta^{18}\text{O}$  minima, are used to identify the annual growth. In shell A, five isotopic cycles with 14 to 28 growth lamellae per year were found and a growth rate of 6.1 to 10.7 mm/a was calculated. Shell B contains 2 complete isotopic cycles with a lower quantity of growth lamellae per year (10 to 24) but an increased growth rate (7.2 to 13.7 mm/a). The annual growth rate of shell C, depicted by  $\delta^{18}\text{O}$  in the LV, is 8.6 mm/a and represented by 22 growth lamellae. Oxygen isotope cycles ( $n=2$ ) and corresponding growth lamellae (83 and 95) identified in shell D provide evidence for a much larger annual growth rate, the latter ranging between 19.5 and 23.1 mm/a. The number of growth lamellae per year of shell A (14-28) and B (10 and 24) is comparable to the dataset of Regidor-Higuera et al. (2007), who counted 16 to 22 growth lamellae per year for a *Radiolites* sp. and 11 to 27 growth lamellae per year for a *P. ciryi*. The longitudinal growth rate varies between 3-4 mm/a (Steuber, 1996) and 3.5-15 mm/a (Regidor-Higuera et al., 2007), which is within the range of shell A and B (6.1 to 13.7 mm/a). Shell D, in contrast, differs significantly with a growth rate of up to

26.4 mm/a, which is caused by the dominance of radial growth over the vertical one (Fig. 5.16). The slower growth rates in the RVs are caused by the vertical growth, which is favoured before the radial (Fig. 5.16) in order to adapt to an unstable environment in a high-energy setting (Steuber, 1996; Pons and Vicens, 2008).

**Fig. 5.16:** Schematic radial (red) and vertical growth (green) of radiolitids (modified after Pons and Vicens, 2008). In the RV vertical (1) dominates radial (2) growth, while in the LV the radial (1) dominates the vertical (2) growth.

### 5.5.3 Palaeoenvironmental implications

In order to reconstruct the prevailing environmental conditions of the shells' living habitat, both petrographic and chemical results were combined. First, the distribution of growth lamellae was used to reconstruct the living position of the shells with regard to the overall marine habitat. In general, growth lamellae are divided into growth lines (dark) and growth increments (light). During emersion phases (low tides), when the shell is closed and the pH value decreases, dark lamellae are produced. During an immersion (high tides), the shell opens and the pH value of the extrapallial fluid increases to values similar to the surrounding water ( $\sim 7.8$ ) and light lamellae are produced (Regidor-Higuera et al., 2007). The durations of the immersion or the emersion phases are responsible for the width of the single lamellae. As the alternation of growth lamellae is often regular, a continuous immersion is assumed with recurring emersion phases in the intertidal domain. An intertidal habitat of rudist shells analysed in this study is in line with the high-energy setting (well-sorted and rounded shell debris) prevailing at the margin of the MLC section. Assuming an intertidal habitat, variations in salinity affect shell isotope records less than a restricted habitat would do. A minor influence of salinity changes on MLC shells was confirmed by the limited variability in  $\delta^{13}\text{C}$  values (amplitude: 1-1.5 ‰), which indicates a maximum change of 2-3 p.s.u. in the surrounding water (Steuber et al., 2005). Furthermore, water temperature variations of the shells' surrounding water were calculated using cyclic variations in the  $\delta^{18}\text{O}$  record (Steuber, 1999). For shell A, B and D similar ranges of seasonal temperature changes were calculated with a  $T_{\text{max}}$  range between 28.66 °C and 33.92 °C and a  $T_{\text{min}}$  range between 22.5 °C and 28.95 °C (Fig. 5.17; Tab. 5.2). Steuber et al. (2005) state that mean temperatures, derived from skeletal carbonates, are not higher than 32°C and that most of the values oscillate in a 20 to 25 °C range for the

early Cretaceous. Especially at the Aptian-Albian transition (106 to 111 Myr), the calculated temperatures from shells found in Spain range between 24 and 25°C. The calculated mean values (~ 28°C) of the here analysed shells are slightly higher but the uncertainty about the  $\delta^{18}\text{O}$  value of the ancient sea due to latitudinal difference and salinity content might cause this deviation (Steuber et al., 2005).

**Fig. 5.17:** The  $\delta^{18}\text{O}$  values and correlated temperature of the surrounding water of shells A (purple), B (green), LV of C (white), D (red) are plotted against the length ( $\mu\text{m}$ ).  $T_{\text{min}}$  and  $T_{\text{max}}$  values from Steuber et al. (2005) are shown as dashed lines.  $T_{\text{range}}$  (ESP) depict the values derived from the successions of Spain (Aptian-Albian transition).

## 5.6 Conclusions

In this study, a first approach was made to combine sclerochronological and chemical results to determine if radiolitids are a valuable archive for palaeoenvironmental reconstruction. In previous studies, radiolitids were rarely used for climate reconstruction due to their porous outer shell structure, as the embedded diagenetic calcite filling the pores might compromise data collection. The following conclusions were formulated based on the data collected within the scope of this study:

- (I) Neither the isotopic nor the elemental datasets indicate a diagenetic alteration of shell A, B, the LV of C and D. Only the RV of shell C, which contains a cement-filled celluloprismatic structure, shows highly variable isotopic and elemental datasets and is therefore classified as diagenetically altered.
- (II) The highly compact LV of shell C and D records a gradually, smooth sine function as  $\delta^{18}\text{O}$  pattern and is therefore a promising archive for palaeotemperature reconstruction.
- (III) The RV of shell A and B, which contains an alternation of compact and non-compact parts, shows often sharply accented shifts to positive values in the  $\delta^{18}\text{O}$  record. Nevertheless, cyclic variations are visible. The temperatures derived from the RVs are within range of temperatures derived from the LVs and are in turn comparable to the temperatures calculated by Steuber et

al. (2005). Therefore, the here analysed radiolitid shells are suitable for palaeoenvironmental reconstructions.

- (IV) Due to regular alternation of the growth lamellae, the intertidal is assumed as former living habitat of the shells. Additionally, large fluctuations in salinity of the surrounding water were excluded due to small oscillations in the  $\delta^{13}\text{C}$  values.

Summing up, the sampling of radiolitid shells shows that it is possible to use them as a palaeoenvironmental archive. Especially the LV is suitable for the reconstruction of palaeotemperatures. The RV can be used as an archive too with the requirement that the celluloprismatic structure is not pronounced. This implies that shells having a structure similar to the RV of C are not suitable material. However, if the shells show a structure like shells A and B, i.e. a variation of compact and non-compact parts, they may be a suitable archive. Before they can be used as such, the common methods need to be applied to exclude diagenetic alteration (cross-plot of isotopic values and elemental data). Celluloprismatic structures as shown in the RV of shell C cannot be used as palaeotemperature archives, but they provide important information about the living habitat of animals.

## **6. Summary and Outlook**

The main point of this thesis is the reconstruction of major environmental events during the mid-Cretaceous on the Apennine Carbonate Platform (ACP). Three main questions were postulated, as seen in 1.5. The following chapter gives a brief summary of this thesis, firstly stating the posed questions followed by the acquired insights.

### **(1) To what extent can a continuous sedimentation of the Apennine Carbonate Platform be confirmed?**

Two sections, the open lagoon Santa Lucia (SL) and the platform marginal Monte La Costa (MLC), located on the Apennine Carbonate Platform, were analysed. Using integrated bio- and chemostratigraphy a precise chronostratigraphic framework was established. During this process, the fragmentary record of the Apennine Carbonate Platform became apparent: The Santa Lucia succession, ranging from Barremian to Cenomanian, reveals that about 61% of the time (~ 20.7 Myr) is lost in three major hiatal surfaces including intervals of the Early Aptian (~ 3.2 Myr), Late Aptian (~ 3.3 Myr) and Middle Albian to uppermost Middle Cenomanian (~ 14.2 Myr). The Late Aptian hiatus is also found in the less expanded Monte La Costa section, dated to Aptian-Albian. The related exposure surfaces were determined and documented, so that their chemical features (e.g. C-anomalies), their field expression (e.g. bauxite, breccia, and soil formation) and the time loss can be compared with each other.

### **(2) When was the onset of the microbial bloom in each analysed section and what environmental conditions can be reconstructed for this period?**

Using the established chronostratigraphic framework, a platform-wide, synchronous onset of pervasive bacinelloid microencrusters in both the inner (Santa Lucia) and marginal (Monte La Costa) carbonate platform domain is dated to the period between the Jacob and Kilian black-shale levels of the Late Aptian OAE1b multi-event. With its initial phase during the late stage of the so-called Late Aptian ‘cold snap’, the detected period of bacinelloid growth gives an insight towards the prevailing environmental parameters during this time: leading from cold temperatures to an increase in temperature and a paralleled significant rise of the sea level.

### **(3) To what extent are radiolitids a viable basis for environmental reconstruction, especially temperature, salinity and habitat?**

Radiolitids, the main carbonate producers of the Apennine Carbonate Platform, are often neglected as a palaeoenvironmental archive. Although they contain an outer shell layer composed of low-Mg calcite, its porous structure poses a challenge for palaeoenvironmental studies. High-resolution sampling, using a combination of elemental and isotopic data as well

as sclerochronological descriptions, shows that the right valve (RV) and the left valve (LV) differ greatly with regard to their usability as archives. The highly compact left valve recorded a gradually, smooth sine function as  $\delta^{18}\text{O}$  pattern and is therefore an excellent archive for palaeotemperature reconstructions. The regular alternation of the growth lamellae of the right valve is an indicator for the intertidal as former living habitat.

By raising three key questions and gathering conclusive insights, this thesis contributes to the unravelling of shallow marine carbonate platforms. With the newly established framework previous biostratigraphically defined sections of the Apennine Carbonate Platform can now be integrated in the generated framework, allowing their more accurate chronostratigraphic dating.

But still, further research opportunities can be proposed for (I) the environmental conditions causing a microbial bloom and (II) the combination of elemental and isotopic data sampling.

- (I) As described in various other studies, several *Lithocodium-Bacinella* occurrences were reported from other sections of the Apennine Carbonate Platform. Before the driving factors of microbial episodes can be deciphered, it is necessary to evaluate the temporal and spatial distribution of microencrusters. By using the newly established framework, a precise dating is made possible, allowing the integration of previously recorded data and achieving a higher degree of temporal accuracy. Since previous studies often show only a vague description of the microencrusters, the comparability of different sections is low. To solve this problem, the morphotypical classification of Rameil et al. (2010) is suggested, to systematically document occurring microencrusters for each section.
- (II) By combining high-resolution sampling of elemental with isotopic data, a promising methodology for palaeoenvironmental reconstruction is created. The first results of the applied isotopic measurements show encouraging results, yielding reliable cyclic patterns of  $\delta^{18}\text{O}$ . Furthermore, using the elemental dataset, diagenetically altered shell material can be quickly detected. For future research, it is important to precisely define and document transects before measurements, to make sure that the obtained datasets can be linked and mapped to the shell. Additionally,  $\mu\text{XRF}$  measurements can be supported with ICP-OES data, to maintain reliable results.

## **7. Author contributions**

Katharina E. Schmitt carried out logging and sampling during field campaigns. She executed all laboratory work (thin-section preparation, sample preparation for IRMS and ICP- OES measurements). She interpreted the analyzed data, wrote all the text including the manuscript chapters 3-5 and prepared all figures and tables.

Stefan Huck conceived and designed the project with input from Ulrich Heimhofer. Stefan Huck coordinated the project and organized external funding. He assisted during field work and with data interpretation and reviewed and improved text and figures of the manuscript chapters 3-5.

Ulrich Heimhofer assisted with data interpretation. Furthermore, he reviewed and improved of the manuscript chapters 3-5.

Gianluca Frijia and Matteo DiLucia established the biostratigraphy used in this thesis.

Malte Krummacker assisted with Micromill-based shell sampling (chapter 5).

Niels de Winter performed  $\mu$ XRF measurement and assisted with data interpretation (chapter 5).

## μXRF MAPPING OF ALL SHELL FRAGMENTS

Overview of the element concentration of Mn, Fe, Mg and Sr using  $\mu$ XRF mapping as well as an original photograph of the shell. No structures are visible in the scans for manganese, iron and magnesium. In shell D, the outlines of the last two elements can be detected. Strontium is the only element that is clearly visible in all four shells. Especially in the shells B, C and D the structures are clearly visible. At C and D, the cap is clearly displayed. In the scans of A and B, on the other hand, single micro and macro structures cannot be distinguished. For A and C no Mg scans are available. Arrow indicates growth direction of the shell.

**μXRF LINE SCAN RAW DATA OF SHELL FRAGMENT A**

Plotted raw data of Mg and Sr of shell D.

Plotted raw data of Mn and Fe of shell D.

## **Acknowledgements**

The last three years have not always been easy, but in the end, they have been a great experience. Of course, many people were involved in this work, be it through their scientific advice or through encouraging words and gestures. But I would still like to thank a few people in particular:

Dr. Stefan Huck, for the opportunity to write this thesis. Whenever I had questions or problems your door was always open to me. During field trips and conferences, you were a great supervisor and friend. Without you, this thesis wouldn't have been possible. I would like to especially thank you for your support during the last months.

Prof. Dr. Ulrich Heimhofer, for the chance to work at the Institute of Geology and in your research group. At any given time, you were always around to help with advice, hints, support and encouragement. Your ideas and corrections during the writing of this thesis and its manuscripts, were always helpful and greatly appreciated.

Prof. Dr. Adrian Immenhauser from the Institute of Geology, Mineralogy and Geophysics (Ruhr-University Bochum), Prof. Dr. Andrea Hampel from the Institute of Geology (Leibniz University Hannover) and Prof. Dr. Francois Holtz from the Institute of Mineralogy (Leibniz University Hannover) are gratefully acknowledged as co-examiners.

Dr. Gianluca Frijia, Dr. Niels de Winter, Dr. Alexis Godet for their collaboration on the manuscripts and/or in the lab. Thank you for your expertise and time.

Christiane Wenske for initiating me into the secrets of the Gasbench and answering every question with great patience.

My colleagues Fanfan, Gang, Katharina, Doris, Janette, Uli M., Fritz, Till and Jörg for their help.

Furthermore, would like to thank: Conny and her Markus, who made the start in Hannover very easy and who were always available for conversations; Lars, as a lovely supporter in challenging personal and academic situations; Nils for the Schnacks in hessian/kölsch dialect during late night shifts; Philipp, for the many analytical and constructive discussions; Schorsch, who always had an open ear; Robert, for semantic lessons, red lines and his precious time. I appreciated all of this.

The gratitude and love I feel for my parents cannot be expressed in words. Thank you for everything you have done. I would like to thank my brother and sister-in-law for their patience, encouragement, help, proof-reading and for giving me the coolest niece in the world! I also thank my best friend HP for being part of my family.

## Curriculum Vitae

### Personal data

---

Name: Katharina Elena Schmitt  
Date of birth: 04.12.1986  
Place of birth: Weilburg  
Nationality: German

### Education and professional career

---

July 2007 A-levels (Gymnasium Philippinum Weilburg)  
Apr. 2008 - Dec. 2013 Diploma degree in geology (Project title: „effects of different preparation, fixation and dying methods on the isotope signature of carbonate samples“ Johannes Gutenberg - University Mainz)  
Aug. 2011 Undergraduate in geology (chemistry, meteorology, mineralogy, general geology)  
Apr. 2012 - July 2013 Research assistant at the Department of Applied and Analytical Palaeontology, University Mainz  
Apr. 2014 - Oct. 2015 Office employee at ARANO GmbH - Provider for technical documentation  
Aug. 2014 Pilot-study for a DFG project in Mexico  
Nov. 2015 PhD student (Project title: Early Cretaceous Shoal Water Carbonates from the Central Apennines – Sedimentology, Chemostratigraphy and Sclerochemistry Leibniz Universität Hannover)
