ABSTRACT

Aluminium (Al) toxicity and drought are two major abiotic stress factors limiting common bean (*Phaseolus vulgaris* L.) production in the tropics. The Al-impeded root growth may strongly limit the water exploitation of roots from subsoil and thus less ability to withstand drought stress in the acid soils. In light of the importance of root development under Al toxicity and drought stress, in this study the short-term effects of combined Al toxicity and drought stress on root growth with special emphasis on physiological and molecular mechanisms in the root apex was investigated.

Using hydroponics, PEG 6000 (polyethylene glycol)-induced osmotic (drought) stress reversed the Al-induced inhibition of root elongation by reducing Al accumulation in the root tips in the Al-sensitive genotype VAX 1, which was related to the reduction of cell-wall (CW) porosity resulting from PEG 6000-induced dehydration of the root apoplast. Less Al stress in PEG-treated roots was confirmed by the expression of the Al-sensitivity indicator genes: multidrug and toxin extrusion family protein (*MATE*) and 1-aminocyclopropane-1-carboxylic acid oxidase (*ACCO*). Transcriptional analysis using SuperSAGE (serial analysis of gene expression) and quantitative RT-PCR (qRT-PCR) suggested that genes related to CW assembling and modification such as xyloglucan endotransglucosylase/hydrolase (*XTH*), glucan endo-1,3-beta-glucosidase (*BEG*) and hydroxyproline-rich glycoprotein (*HRGP*) play important roles in PEG-induced decrease of CW porosity leading to reduced Al accumulation in root tips. A large-scale proteomic analysis revealed that dehydrin (DHN) may play a key role in the protection of osmotic stress-induced physical breakage of CW and thus the maintenance of reversible CW extensibility.

Under soil conditions, drought reduced Al toxicity in the common bean genotype VAX 1, indicated as the reversion of Al-induced enhancement of callose content and of *MATE* gene expression in the root tips. However, in contrast to PEG-induced reduction of Al injury in hydroponics, combined Al and drought stress in soil resulted in a more severe inhibition of root elongation than either stress alone. This is consistent with enhanced further up-regulation by Al of the drought-induced *ACCO* gene involved in the biosynthesis of ethylene by Al and the down-regulation by Al of drought-induced genes/transcription factors in the root tips: the 9-cis-epoxycarotenoid dioxygenase (*NCED*) gene involved in ABA biosynthesis, the transcription factors *bZIP* and *MYB* involved in the regulation of ABA-dependent genes, the ABA-dependent sucrose synthase (*SUS*) gene, the late embryogenesis abundant (*PvLEA18*) gene, the KS-type dehydrin (*KS-DHN*) gene, and the lipid transfer family protein (*LTP*) gene.

Together, the results provide circumstantial evidence that PEG-induced osmotic stress and low soil moisture alleviates Al toxicity, but Al renders the root apex more sensitive to low soil moisture particularly by impacting the gene regulatory network involved in ABA signal transduction and ABA signal cross-talk with other phytohormones necessary for maintaining root growth under drought.

Key words: aluminium toxicity and drought stress, common bean, cell wall porosity

KURZZUSAMMENFASSUNG

Aluminium (Al)-Toxizität und Trockenstress sind zwei wichtige abiotische Stressfaktoren, die die Produktivität von Buschbohne (*Phaseolus vulgaris* L.) in den Tropen begrenzen. Durch Al-Angebot gehemmtes Wurzelwachstum kann die Wasseraufnahme aus dem Unterboden stark beeinträchtigen und damit die Trockenresistenz von Buschbohne auf sauren Böden vermindern. Angesichts der Rolle des Wurzelwachstums für Al-Toxizität und Trockenstress wurde in dieser Arbeit die kurzfristige Wirkung von kombiniertem Al und Trockenstress auf das Wurzelwachstum mit besonderer Berücksichtigung physiologischer und molekularer Mechanismen in der Wurzelspitze untersucht.

In Hydroponik verminderte PEG 6000 (Polyethylenglycol) induzierter osmotischer (Trocken) Stress die Hemmung des Wurzelängenwachstums durch Al durch eine verminderte Al Akkumulation in der Wurzelspitzen im Al-sensitiven Buschbohnen-Genotyp VAX 1. Dies wurde zurückgeführt auf eine Verminderung der Zellwandporosität hervorgerufen durch die Dehydrierung des Wurzelapoplasten durch PEG. Geringerer Al Stress in PEG behandelten Wurzeln wurde bestätigt durch eine verminderte Expression Al-sensitiver Indikatorgene: multidrug and toxin extrusion family protein (*MATE*) und 1-aminocyclopropane-1-carboxylic acid oxidase (*ACCO*). Eine Transcriptionsanalyse mit SuperSAGE (serial analysis of gene expression) and quantitative RT-PCR (qRT-PCR) ergab, dass an der Zellwandsynthese und -struktur beteiligte Gene wie z.B. Xyloglucan endotransglucosylase/hydrolase (*XTH*), Glucan endo-1,3-beta-glucosidase (*BEG*) und Hydroxyproline-rich glycoprotein (*HRGP*) eine wichtige Rolle bei der durch PEG verursachten verminderten Zellwandporosität, die zu einer verminderten Al Akkumulation in Wurzelspitzen führt, spielen. Eine umfassende proteomische Analyse ergab, dass Dehydrin eine Schlüsselrolle für den Schutz der Zellwand vor irreversibler Schädigung durch Entwässerung bei osmotischem Stress durch PEG zukommen könnte.

Im Boden führte Trockenstress zu verminderter Al Toxizität. Hierauf ließ eine geringere Al-induzierte Kallose-Bildung und Expression des *MATE* Genes schließen. Im Unterschied zu einer geringeren Hemmung des Wurzelwachstums durch Al in Gegenwart von PEG in Hydroponik, erhöhte Al-Angebot im Boden die Hemmung des Wurzelwachstums durch Trockenstress. Dies ist konsistent mit einer verstärkten Heraufregulierung durch Al des an der Ethylen-Synthese beteiligten *ACCO* Gens und der Herunterregulierung durch Al von durch Trockenstress verstärkt exprimierten Genen/Transkriptionsfaktoren in den Wurzelspitzen: des an der ABA-Synthese beteiligten 9-cis-Epoxycarotenoid dioxygenase (*NCED*) Gens, den Transkriptionsfaktoren *bZIP* and *MYB*, die an der Regulation ABA abhängiger Gene beteiligt sind, des ABA abhängigen Sucrose synthase (*SUS*) Gens, des Late embryogenesis abundant (*PvLEA18*) Gens, des KS-type dehydrin (*KS-DHN*) Gens und des Lipid transfer family protein (*LTP*) Gens. Insgesamt lassen die Ergebnisse darauf schließen, dass PEG induzierter osmotischer Stress und Trockenstress Al Toxizität vermindern. Aluminium-Angebot im Boden macht die Wurzelspitze allerdings empfindlicher gegenüber Trockenstress, da Al insbesondere das die ABA Signaltransduktion regulierende Gen-Netzwerk und die Kommunikation von ABA mit anderen Phytohormonen, was Voraussetzungen für die Aufrechterhaltung des Wurzelwachstums unter Trockenstress sind, beeinträchtigt.

GENERAL INTRODUCTION

Acid soils and major constraints

Soil acidity with $\text{pH} \leq 5.5$ is one of the most important factors limiting crop production worldwide on approximately 30% of the world's total land area and as much as 50% of the world's potentially arable lands. The tropics and subtropics account for 60% of the acid soils in the world. In tropical areas about 43% of soils are acidic comprising about 68% of tropical America, 38% of tropical Asia, and 27% of tropical Africa (von Uexküll and Mutert, 1995). The factors that contribute to acid soil infertility and subsequent stunted plant growth in acid soils are complex. In acid mineral soils, a variety of individual chemical constraints and interactions among them limit plant growth. For example, in low pH soils, it is not usually the hydrogen ion toxicity which affects plant growth but rather other toxicities, such as aluminium (Al) and manganese, and deficiencies of phosphorus, nitrogen, potassium, calcium, magnesium, sulfur, zinc, and molybdenum (Rao et al., 1993). Aluminium toxicity is particularly severe at soil pH values of 5.0 or below (Foy, 1974). And on many acid soils, dry spells during the main growing period of crops are becoming an increasingly important yield-limiting factor (Welcker et al., 2005) with the changing global climate. The use of lime, phosphate fertilizers, organic matter and irrigation is more productive on acid soils, as practiced in the temperate climates of North America and Europe. However, it is not an economically realistic alternative in many developing tropical countries because the high cost is beyond the ability of low input resource-poor farmers. Also, the utilization of fertilizers or chemicals may seriously threaten the environment (Rao et al., 1993; Miklas et al., 2006). On the other hand, even if liming can raise soil pH and overcome toxicity problems, the subsoil usually remains unaffected, since deep lime incorporation is technically difficult and even more expensive.

The traits of aluminium toxicity in plants

When the soil pH drops below 5, Al^{3+} is solubilized into the soil solution and become a major constraint for plant growth and development in acidic soils (Kinraide et al., 1992). The easily observable symptom of Al toxicity is a rapid (minutes to few hours) inhibition of root growth (Horst et al., 1992; Delhaize and Ryan, 1995), resulting in a reduced and damaged root system that limits mineral nutrient and water uptake (Kochian et al., 2004). The rapidity of this response indicates that Al first inhibits root cell-expansion and

elongation and consequently cell division over the longer term (Kochian, 1995; Delhaize and Ryan, 1995). The role of the root apex in the perception of Al toxicity was firstly proposed by Ryan et al. (1993) in maize (*Zea mays*). Subsequently, Sivaguru and Horst (1998) specified that the distal part of the transition zone (DTZ, 1-2 mm) is the most Al-sensitive apical root zone in Al-sensitive maize cultivar 'Lixis'. In common bean, Rangel et al. (2007) showed that both the transition zone (TZ, 1-2 mm) and elongation zone (EZ) are targets of Al injury. It has been suggested that the Al toxicity results from the interactions of Al with either apoplastic (Horst, 1995; Blamey, 2001; Horst et al., 2010), plasma membrane (Zhao et al., 1987; Wagatsuma et al., 1985; Ishikawa and Wagatsuma) or symplastic targets (Kochian, 1995; Barceló and Poschenrieder, 2002; Kochian et al., 2005). However, the mechanisms of Al-induced inhibition of root elongation are still not well defined. Recently, it has been speculated that the Al-induced inhibition of root growth is due to enhanced gene expression and enzyme activity of 1-aminocyclopropane-1-carboxylic acid oxidase (ACCO) resulting in increased ethylene production in *Lotus japonicus* and *Medicago truncatula* (Sun et al., 2007) and the ethylene-mediated inhibition of polar auxin transport controls Al-induced inhibition of root elongation in *Arabidopsis* (Kollmeier et al., 2000; Sun et al., 2010). Also in common bean, Eticha et al. (2010) observed that initial Al-induced inhibition of root elongation was correlated with the expression of the ACCO gene, which is involved in the ethylene biosynthesis, in both common bean genotypes, Quimbaya (Al-resistant) and VAX 1 (Al-sensitive).

The induction of callose synthesis has been proposed as another sensitive indicator of Al injury in roots (Wissemeier et al., 1987; Staß and Horst, 2009), particularly in the root apex (Wissemeier and Horst, 1995; Sivaguru et al., 2006). The high sensitivity of Al-induced callose formation to Al is also a reliable parameter for the classification of genotypes of different plant species in terms of Al resistance (Wissemeier et al., 1992; Horst et al., 1997; Collet and Horst, 2001; Eticha et al., 2005).

The role of the root apoplast in aluminium toxicity and resistance

The accumulation of Al in the root tips is characterized by a rapid initial phase and a low rate at later stages (Zhang and Taylor, 1989; 1990). The rapid initial phase reflects the binding of Al in the apoplast (Taylor et al., 2000; Wang et al., 2004; Horst et al., 2007; Rangel et al., 2009) in which the negatively charged carboxylic groups of pectin provide the Al³⁺ binding sites (Blamey et al., 1990; Chang et al., 1999). The negative charge of pectin depends on its degree of methylation (Eticha et al., 2005), which is controlled by

pectin methylesterase (PME) (Bordenave, 1996; Gerendás, 2007). Schmohl et al. (2000) provided evidence that the degree of methylation (DM) of CWs modulates the Al accumulation and Al sensitivity of maize suspension cells. Also, short-term PME treatment of intact maize roots elevated Al accumulation and Al-induced inhibition of root elongation (Horst et al., 2007). It has been reported that short-term Al accumulation of roots was closely related to the pectin content in apical root sections of maize and faba bean (*Vicia faba*) and the binding of Al to the pectic matrix was closely positively correlated with Al-induced callose formation and thus Al sensitivity (Horst et al., 1999).

The high affinity of Al to the pectic matrix may prevent the binding of Ca^{2+} to the CW, which plays a key role in controlling CW extensibility by the formation and cleavage of Ca bonds during cell elongation (Boyer, 2009). It has been revealed that Al treatment reduces root CW extensibility (Tabuchi and Matsumoto, 2001; Ma et al., 2004). Strong binding of Al to the pectic matrix may present CW extension physically and/or physiologically by decreasing the effectiveness of CW-loosening enzymes (Wehr et al., 2004). Recently, Yang et al. (2011) observed that the Al-induced reduction of the activity of CW loosening enzyme xyloglucan endotransglucosylase (XET) was related to Al-inhibited root elongation in *Arabidopsis*, and the reduction of the activity of this enzyme was accompanied with callose deposition in roots. Therefore, it appears the binding of Al to pectins is closely related to Al sensitivity, since it was also reported that the Al-induced increase in pectin content of Al-sensitive cultivars was greater than that of Al-resistant cultivars (Eticha et al., 2005; Yang et al., 2008). Also in common bean, Rangel et al. (2009) found that the Al-induced root growth was closely negatively related to free apoplastic and particularly strongly bound CW Al. This suggests that the strong binding of Al to the pectic matrix of the CW is a main factor in Al toxicity rather than a resistance mechanism in common bean. However, some studies indicated that the increased pectin content was related to Al resistance (Van et al., 1994) since the free carboxyl groups of pectin can bind or chelate Al^{3+} ions and cause cross-link of pectin molecules (Klimashevskii and Dedov, 1975).

In fact, the involvement of pectin in Al resistance mainly depends on its degree of methylation (DM), since the DM is responsible for the negativity of the CW as mentioned above. In *Petunia inflata*, higher Al accumulation and callose production in the roots and more inhibition of root growth were found in transgenic potato plants with higher PME expression than wild type when exposed to Al (Schmohl et al., 2000). In two differential Al-resistant cultivars of maize, Eticha et al. (2005) observed that the Al-sensitive cultivar

had lower DM and more Al accumulation, and thus were more severely injured by Al compared with the Al-resistant cultivar, while no difference was found in pectin content. Similarly, in rice (*Oryza sativa*), Yang et al. (2008) found that CW PME activity in the root tips was higher leading to a higher demethylated pectin content in the Al-sensitive cultivar than the Al-resistant cultivar. This indicates that the higher proportion of free pectic acid residues in the CW causes a corresponding higher Al accumulation in the root tips and the CW. Also, transcriptional analysis of Al resistance in maize by Maron et al. (2008) revealed that Al up-regulated the expression of *PME* gene in both Al-resistant and Al-sensitive genotypes, while the level of up-regulation of PME was higher in Al-sensitive genotypes.

On the other hand, there is no doubt that more Al accumulation in the CW will also affect the plasma membrane. The interaction between CW and plasma membrane appears to be potentially harmful (Delhaize and Ryan, 1995), although the low rates of transport observed through the plasma membrane will favor the accumulation of Al in the apoplast (Rengel and Reid, 1997). It has been proposed that the interaction of apoplastic Al with the cell wall - plasma membrane - cytoskeleton continuum play major role in the Al-induced inhibition of root growth (Horst et al., 1999; Sivaguru et al., 2000).

Aluminium exclusion from the apoplast by the release of organic acid anions

It is widely accepted that the release of Al-complexing solutes, particularly organic acid anions, from the root apex, play a key role in Al resistance by complexation of Al and thereby detoxifying rhizotoxic Al (Ma et al., 2007; Ryan et al., 2001; Kochian et al., 2004; Delhaize et al., 2007; Ryan and Delhaize, 2010; Horst et al., 2010). It has been well established that the Al-induced release of malate in wheat (*Triticum aestivum*) (Delhaize et al., 1993), citrate in maize, soybean (*Glycine max*) and common bean (Miyasaka et al., 1991; Kollmeier et al., 2001; Yang et al., 2000; Rangel et al., 2010), and oxalate in buckwheat (*Fagopyrum esculentum*) (Zheng et al., 1998). In common bean, Rangel et al. (2010) showed that the initial (0-4 h) genotype-independent Al injury was related to the absence of citrate exudation from the root tips in both genotypes (Quimbaya, Al-resistant; VAX-1, Al-sensitive) in spite of high amounts of citrate in the root apical tissues particularly in Quimbaya. Thereafter (5-9 h), in both genotypes recovery of root elongation was related to an Al-enhanced exudation of citrate typical for pattern-II type Al-induced release of organic acid anions (Ma et al., 2001).

The role of the metabolism of organic acids in Al resistance is still under debate. Most studies have shown no clear relationship between the root content and exudation of organic acid anions (Ryan et al., 2001). Ryan and Delhaize (2010) suggested that the convergent evolution of Al resistance in Al-excluder species mainly resulted from the mutation of transport proteins. However, some evidences indicate that the release of organic acid requires enhanced synthesis of organic acids to maintain the cytosolic pool. For example, in maize, Kollmeier and Horst (2001) showed that an Al-sensitive cultivar was not capable of maintaining the level of citrate in the root apical tissues in spite of a lower exudation rate. This was in agreement with Al-enhanced activities of enzymes involved in citrate synthesis such as malate dehydrogenase (MDH) and phosphoenolpyruvate carboxylase (PEPC) (but not citrate synthase (CS)) in the Al-resistant cultivar and of citrate degradation aconitase (ACO) in the Al-sensitive cultivar. Similarly, in common bean, Rangel et al. (2010) revealed that citrate release requires the activation or expression of an organic anion permease in the plasma membrane and is initially mainly derived from the internal organic acid pool. The sustained recovery from Al stress through citrated exudation in the Al-resistant genotype Quimbaya after 24 h Al treatment relied on restoring the internal citrate pool and a constitutively high activity of CS fuelled by high PEPC activity, while, in the Al-sensitive genotype VAX 1 the citrate exudation, and thus Al exclusion and root elongation, could not be maintained due to the exhaustion of the internal citrate pool and low CS and PEPC activities.

Genes encoding organic acid anion transporters in the plasma membrane belonging to two families, ALMT (Al-activated malate transporter) and MATE (multidrug and toxic compound extrusion) have been identified to mediate the exudation of organic acid anions from the root and thus Al resistance. The ALMT facilitate malate efflux in plant species that depend on malate exudation as the main Al resistance mechanism (Sasaki et al., 2004; Delhaize et al., 2004; Hoekenga et al., 2006; Ligaba et al., 2006), and the MATE proteins play a decisive role in Al-induced citrate exudation (Furukawa et al., 2007; Magalhaes et al., 2007; Ryan et al., 2009). However, these genes related to Al resistance, they may not fully explain the genotypic variation (Ryan et al., 2011), which may depend on the plant species. For example, in sorghum (*Sorghum bicolor*), *SbMATE* was expressed only in the root tips of the Al-resistant genotype in an Al-inducible way (Magalhaes et al., 2007). Similarly, in barley (*Hordeum vulgare*) *HvMATE* expression in the root apices correlated with Al-activated citrate exudation and Al resistance in a set of barley cultivars (Furukawa et al., 2007). However, in contrast to these plant species, studies in common bean showed,

that the *MATE* gene was highly expressed by Al within 4 hours of treatment in both an Al-resistant (Quimbaya) and an Al-sensitive (VAX 1) genotype. The expression of *MATE* was a prerequisite for citrate exudation, but the build-up of Al resistance within 24 h in Quimbaya exclusively depended on the capacity to sustain the synthesis of citrate for maintaining the cytosolic citrate pool that enabled continuous exudation (Eticha et al., 2010; Rangel et al., 2010).

The response of roots to drought

When plants are grown in drying soil, the growth of shoots is rapidly inhibited (Van Volkenburgh and Boyer, 1985; Chazen and Neumann, 1994) while in contrast, roots can still maintain elongation (Westgate and Boyer, 1985; Sharp et al., 1988). The differential response of roots and shoots to drought is considered an important feature of the adaptation of plants to water-deficit conditions since the maintenance of the root elongation facilitates water exploitation from deep soil (Sharp and Davis, 1989; Wu and Cosgrove, 2000; Sharp et al., 2004). It has been found that the elongation is maintained preferentially towards the root apex during water deficit (Sharp et al., 1988). Detailed studies indicate that root elongation was maintained in the apical 0-3 mm in maize (Liang et al., 1997; Spollen and Sharp, 1991) and 0-4 mm in soybean (Yamaguchi et al., 2010) under reduced water supply. It has been proposed that three potential mechanisms are involved in the maintenance of root elongation under low soil moisture conditions: (i) osmotic adjustment; (ii) modification of cell-wall extension; (iii) the accumulation of abscisic acid (ABA) (Sharp et al., 2004; Yamaguchi and Sharp, 2010).

The deposition of osmotica in the root tips appears most important to maintain the turgor of cells during limited water supply. It was reported that the rate of proline deposition increased dramatically along the root apex under drought conditions, and the resulting enhancement in proline accumulation was responsible for about 45% of the total osmotic adjustment (Voetberg and Sharp, 1991; Yamaguchi and Sharp, 2010). However, the role of other osmolytes such as the widely recognized cellular solutes sugars, amino acids, organic acids and inorganic ions (Morgan, 1984) for osmotic adjustment cannot be disregarded since dehydration resulting from osmotic stress increased sugar (fructose, glucose and sucrose) accumulation in the roots of mung bean (*Vigna mungo*) seedlings (Itoh et al., 1987).

Although the osmotic adjustment is a prerequisite for root elongation, it is insufficient to

maintain root growth under drought, since it additionally requires maintenance of CW extensibility (Sharp et al., 2004; Yamaguchi and Sharp, 2010). It appears that the modification of CW composition is important for the maintenance of CW structure and the avoidance of CW collapse during water loss from the apoplast. Since the water is the most abundant component of the CW making up about two thirds of the CW mass in growing tissues (Cosgrove, 1997), the loss of water from the CW matrix probably will result in serious disruption to polymer organization and consequently polymers will be brought in close proximity to each other, thus causing polymer adhesion or cross-linking (Moore et al., 2008). Cellulose microfibrils are the major tensile components of the wall and interact with the matrix components such as hemicellulose, pectin and structural proteins (Cosgrove, 2005). The interaction between the polymers endow the wall with strength or stiffness, whereas during the elongation the primary CW still allows the CW expansion, which can be modified by several CW-loosening enzymes such as expansin, XET and glucanase, or the synthesis and integration of new elements into the CW from the symplast (Wu and Cosgrove, 2000). Maize roots subjected to drought treatment have demonstrated that the CW of the apical 0-3 mm segments of root tips maintains a flexible state and thus allows elongation to continue (Wu and Cosgrove, 2000; Fan and Neumann, 2004), while the segments of 3-9 mm region of root apex remain inextensible leading to a cessation of further growth in this apical root section (Fan et al., 2006). The cessation of root growth in the basal region of the root apex is supposed to result from the accumulation of phenolics and lignin (Fan and Neumann, 2004). Usually the phenolics and lignin monomers can covalently cross-link the wall matrix via peroxidase and oxidase enzymes. The phenolic cross-links will tighten the wall structure, while lignin formation is accompanied by removal of water from the wall (Brett and Waldron, 1996; Moore et al., 2008). The apical walls increase in extensibility, and thus elongation has been shown to be related to the enhancement of expansin and XET activity (Wu et al., 1994; 1996). However, there is also evidence showing that drought did not affect the XET activity in the root tips region, when maize roots were exposed to polyethylene glycol (PEG)-simulated water deficit (Pritchard et al., 1993). Also a proteomic analysis of root apical CW proteins showed that water deficit even decreased the XET formation particularly in the apical 0-3 mm region of maize root apex (Zhu et al., 2007).

In addition, the accumulation of ABA in the root tips has been shown to be required for the maintenance of maize primary root elongation at low water potentials (Sharp et al., 2004). Using the ABA-deficient mutant *vp5* and a chemical inhibitor of ABA biosynthesis

to decrease endogenous ABA levels in seedlings growing at low water potentials, Sharp et al. (2004) reported that reduced ABA accumulation in maize primary roots was associated with more severe inhibition of root elongation. Under drought, ABA accumulated mainly towards the root apex (Saab et al., 1992) indicating that it was required for the maintenance of elongation in the distal elongation zone at low water potentials (Yamaguchi and Sharp, 2010). Several studies have clearly shown that ABA can suppress ethylene production, and the maintenance of root elongation under water deficit conditions requires increased ABA levels to prevent excess ethylene production (Sharp et al., 2000; Spollen et al., 2000; Sharp, 2002; LeNoble et al., 2004). Also it is suggested that ABA accumulation may play an important role in cellular protection from reactive oxygen species (ROS)-induced oxidative damage in drought-subjected roots of both maize and soybean (Yamaguchi and Sharp, 2010). Using the ABA-deficit mutant *vp14*, they found that the primary root elongation zone exhibits an enhanced cytosolic ROS level under drought conditions.

Common bean: An aluminium and drought-sensitive crop

Common bean (*Phaseolus vulgaris* L.) is the most important grain legume for direct human consumption worldwide, and it is a staple crop for small farmers and the urban poor in many Latin American and African countries. Total production exceeds 23 million metric tones, of which 7 million metric tones are produced in Latin America and Africa. It is also the second important source of protein (65% of all protein consumed) and the third most important caloric source (32% of all calories consumed) after cassava (*Manihot esculenta* Crantz) and maize (*Zea mays* L.) (Rao, 2001; Broughton et al., 2003). The higher production of beans can bring more profit for small farmers in less developed countries of Latin American and Africa. However, under field conditions, the production of common bean in the tropics is often limited by two major abiotic stresses, Al toxicity and drought (Thung and Rao, 1999; Singh, 2001; Ishitani et al., 2004). About 40% of the common bean-production areas in Latin America and 30 to 50% of central, eastern, and southern Africa are affected by Al phytotoxicity resulting in yield reduction from 30 to 60% (CIAT, 1992). And as much as 60% of the common bean production in the developing world occurs under conditions of drought stress (Graham and Ranalli, 1997; Beebe et al., 2008) and consequently leads to a low average global yield ($< 900 \text{ kg ha}^{-1}$) of beans (Singh, 2001; Thung and Rao, 1999). Since the major phytotoxic site of Al is the root apex and the inhibition of root elongation is the primary symptom of Al toxicity (see above), the exploitation of the subsoil for water and thus the ability of the plants to withstand drought

stress may be strongly impeded by Al toxicity in acid subsoils (Goldman et al., 1989). Thus on acid soils that physically permit deep rooting both Al and drought resistance are required for yield improvement particularly in common bean, a generally Al and drought-sensitive crop (Rao, 2001; Beebe et al., 2008). Studies on these two combined growth and yield limiting factors are important and necessary to clarify the opportunities and constraints in breeding for adaptation to these abiotic stresses.

Based on the above information, the short-term effects of combined Al toxicity and drought on root growth with special emphasis on Al/drought interaction in the root apex was investigated at physiological and molecular level in the present study:

- (i) Physiological analysis of the interaction between Al toxicity and PEG-simulated drought stress in common bean grown in hydroponics (Chapter 1).
- (ii) Transcriptional analysis of the interaction between Al toxicity and PEG-simulated drought stress in common bean grown in hydroponics (Chapter 2).
- (iii) Proteomic analysis of the PEG-simulated drought stress in root tips of common bean grown in hydroponics (Chapter 3).
- (iv) Physiological and molecular analysis of the interaction between Al toxicity and drought stress in common bean under soil conditions (Chapter 4).

CHAPTER 1

Alteration of cell-wall porosity is involved in osmotic stress-induced enhancement of aluminium resistance in common bean (*Phaseolus vulgaris* L.)

Abstract

Aluminium (Al) toxicity and drought are the two major abiotic stress factors limiting common bean production in the tropics. Using hydroponics, we investigated short-term effects of combined Al toxicity and drought stress on root growth and Al uptake into the root apex. In the presence of Al stress, PEG 6000 (polyethylene glycol)-induced osmotic (drought) stress lead to amelioration of Al-induced inhibition of root elongation in the Al-sensitive genotype VAX 1. PEG 6000 (>> PEG 1000) treatment greatly decreased Al accumulation in the 1-cm root apices even when the roots were physically separated from the PEG solution using dialysis membrane-tubes. Upon removal of PEG from the treatment solution, the root tips recovered from osmotic stress and the Al accumulation capacity was quickly restored. The PEG-induced reduction of Al accumulation was not due to lower phyto-toxic Al concentration in the treatment solution, reduced negativity of the root apoplast, or enhanced citrate exudation. Also cell-wall (CW) material isolated from PEG-treated roots showed a low Al-binding capacity which, however, was restored after destroying the physical structure of the CW. The comparison of the Al^{3+} , La^{3+} , Sr^{2+} , and Rb^{+} binding capacity of the intact root tips and the isolated CW revealed the specificity of the PEG 6000 effect for Al. This could be due to the higher hydrated ionic radius of Al^{3+} compared to other cations ($\text{Al}^{3+} \gg \text{La}^{3+} > \text{Sr}^{2+} > \text{Rb}^{+}$).

In conclusion, the results provide circumstantial evidence that the osmotic stress-inhibited Al accumulation in root apices and thus reduced Al-induced inhibition of root elongation in the Al-sensitive genotype VAX 1 is related to the alteration of CW porosity resulting from PEG 6000-induced dehydration of the root apoplast.

Keywords: aluminium, apoplast, drought stress, intercellular space, organic acids, polyethylene glycol, root elongation

Introduction

Soil acidity (pH < 5.5) is one of the important limitations to crop production worldwide. Acid soils make up approximately 30% of the world's total land area and more than 50% of the world's potentially arable lands, particularly in the tropics and subtropics (von Uexküll and Mutert, 1995; Kochian et al., 2004). When the pH drops below 5, aluminium (Al) is released into the soil solution and becomes the single most important factor limiting crop production on 67% of the total acid soil area (Eswaran et al., 1997).

Common bean (*Phaseolus vulgaris* L.) is the most important food legume for direct human consumption in the world, and it is a staple food crop for small farmers and the urban poor in many Latin American and African countries. It is also the second most important source of protein (65% of all protein consumed) and the third most important caloric source (32% of all calories consumed) after cassava (*Manihot esculenta* Crantz) and maize (*Zea mays* L.) (Rao, 2001; Broughton et al., 2003). Under field conditions, common bean often experiences different abiotic stresses including drought, toxicities of Al and manganese, low soil fertility, and high temperatures (Thung and Rao, 1999; Singh, 2001; Ishitani et al., 2004). Among these, Al toxicity and drought are the two major abiotic stresses for bean production in the tropics (Ishitani et al., 2004). About 40% of the common bean-production areas in Latin America and 30 to 50% of central, eastern, and southern Africa are affected by Al phytotoxicity resulting in yield reduction from 30 to 60% (CIAT, 1992).

The easily observable symptom of Al toxicity is a rapid (minutes to few hours) inhibition of root growth (Horst et al., 1992; Delhaize and Ryan, 1995), resulting in a reduced and damaged root system that limits mineral nutrient and water uptake (Kochian et al., 2004). Ryan *et al.* (1993) found that the root apex is the most Al-sensitive root zone, and Sivaguru and Horst (1998) identified the distal transition zone (DTZ) as the specific site of Al injury in maize. However, in common bean, Rangel et al. (2007) showed that both the transition zone (TZ, 1-2 mm) and elongation zone (EZ) are targets of Al injury. Aluminium resistance was related to a lower Al accumulation in the root tip (Shen et al., 2002; Rangel et al., 2007). Under short-term Al supply Al accumulates primarily in the root apoplast (Taylor et al., 2000; Wang et al., 2004; Rangel et al., 2009), where Al³⁺ strongly binds to the negatively charged binding sites (Zhang and Taylor, 1989; Blamey et al., 1990; Horst et al., 2010) provided by unmethylated pectin in the cell wall (CW) (Schmohl et al., 2000; Eticha et al., 2005). Thus, a lower CW negativity reducing Al

accumulation (Horst, 1995) and the detoxification of Al in the apoplast through root exudates play an important role in Al resistance. Lower Al accumulation in the root tips and thus Al resistance is mediated by citrate exudation in common bean (Mugai et al., 2000; Shen et al., 2002; Rangel et al., 2010).

Drought stress is another important limiting factor for common bean production in the developing world, since as much as 60% of the common bean production occurs under conditions of drought stress (Graham and Ranalli, 1997; Beebe et al., 2008). Particularly on many acid soils, dry spells during the main growing period of crops are a major yield-limiting factor (Welcker et al., 2005). Adaptation to drought involves complex multigenic components that interact holistically in plant systems (Cushman and Bohnert, 2000). In plants growing in dry soil, both shoot and root growth is hampered (Westgate and Boyer, 1985; Sharp et al., 1988). The maintenance of root growth during water deficit facilitates water uptake from the subsoil (Sponchiado et al., 1989; Serraj and Sinclair, 2002). However, the exploitation of the subsoil for water and thus the ability of the plants to withstand drought stress may be strongly impeded by Al toxicity in acid subsoils (Goldman et al., 1989). Thus on acid soils that permit deep rooting both Al and drought resistance are required for yield improvement particularly in common bean, a generally Al and drought-sensitive crop (Rao, 2001; Beebe et al., 2008). Therefore, studies on individual and combined stress factors of these two limitations are important to clarify the opportunities and constraints in breeding for adaptation to these abiotic stresses.

In light of the importance of root development under conditions of Al toxicity and drought, short-term effects of combined Al toxicity and drought stress on root growth with special emphasis on Al/drought interaction in the root apex was investigated in the present study in hydroponics which allow a detailed study of Al toxicity. Drought stress was imposed through the application of polyethylene glycol (PEG). PEG 6000 is a high molecular weight solute, which cannot enter the apoplastic space (Carpita et al., 1979, Hohl and Schopfer, 1991). It thus is being amply used as a non-absorbed osmoticum to induce osmotic stress and allows to mimic the response of plants to drought stress in hydroponic studies (Jia et al., 2001; Fan and Neumann, 2004).

Materials and Methods

Plant materials and growing conditions

Seeds of the four common bean genotypes, Quimbaya, G 21212, BAT 477 and VAX 1 were germinated in filter paper sandwiched between sponges. After three to four days, uniform seedlings were transferred to a continuously aerated simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl and 8 μM H₃BO₃ (Rangel et al., 2007). Plants were cultured in a growth chamber under controlled environmental conditions of a 16/8 h light/dark cycle, 27/25 °C day/night temperature, 70% relative air humidity, and a photon flux density of 230 μmol m⁻² s⁻¹ of photosynthetically active radiation at plant height. The pH of the nutrient solution was gradually lowered to 4.5 within two days. Then the plants were transferred to treatment solutions containing a factorial combination of Al (0, 25 μM) and PEG 6000 (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) (0, 200 g L⁻¹) for 24 h in the simplified nutrient solution, pH 4.5. At harvest, the culture solutions were collected and filtered immediately through 0.025 μm nitrocellulose membranes. Mononuclear Al (Al_{mono}) concentrations were measured colorimetrically using the pyrocatechol violet method (PCV) according to Kerven et al. (1989). The Al_{mono} concentration of the Al treatment solution was kept at 25 μM by adding Al stock solution when necessary to prevent a decrease of the Al_{mono} concentration in the solution owing to the Al absorption by the roots. There was no difference between the PEG treatments (data not shown), suggesting that PEG supply did not lead to precipitation or complexation of Al in the treatment solution.

If not otherwise mentioned PEG 6000 (PEG) was used. In some experiments different PEG 6000 concentrations were used. The corresponding osmotic potentials (OPs) of the 0, 50, 100, 150, 200 and 250 g L⁻¹ PEG 6000 solutions were 0.00, -0.06, -0.24, -0.60, -1.20 and -2.10 MPa, respectively, measured with a cryoscopic osmometer (Osmomat 030, Gonotec GmbH, Berlin, Germany).

Dialysis membrane-tubes (DMTs) (3,500 Dalton MWCO, Spectra/Por, California, USA) were used to separate the roots from the PEG 6000 solution. After 2 days of acclimation, plants were transferred into DMTs, and then the DMTs were transferred into 200 g L⁻¹ PEG treatment solution and kept in an upright position in solution for 8 h, then the DMTs were transferred to 100 μM Al treatment solution without or with 200 g L⁻¹ PEG for 1 h. In parallel, experiments without DMT were conducted for comparison. The PEG and Al

concentrations in the parallel experiments were 150 g L^{-1} and $25 \text{ }\mu\text{M}$, respectively. When treating the plants in the DMTs with 200 g L^{-1} PEG and $100 \text{ }\mu\text{M}$ Al, inhibition of root elongation and Al contents were comparable to the treatment of the plants without DMTs at 150 g L^{-1} PEG and $25 \text{ }\mu\text{M}$ Al, respectively (data not shown). Thus different concentrations of Al and PEG were used in the different growing systems.

Diffusion of low molecular weight (LMW) PEG through DMTs and the effect of LMW PEG on root growth and Al accumulation in the root apex

Two hundred fifty ml PEG 6000 (200 g L^{-1}) solution in DMTs was incubated in 1.0, 1.5, and 2.0 L distilled water for 4 h. During this period, the external solution was stirred gently and subsamples were collected in 15 min interval. In these samples the OP was determined with a cryoscopic osmometer either directly or after concentrating ten times with a rotational-vacuum-concentrator RVC 2-25 (Martin Christ Gefriertrocknungsanlagen GmbH, Osterode/Harz, Germany).

To compare the effect of different molecular weight PEG on root growth and Al accumulation in root apices, plants were pre-treated with PEG 1000, 3000 and 6000 (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) at different OPs (0, -0.06, -0.24, -0.60 MPa) for 8 h in simplified nutrient solution, pH 4.5. Then half of the plants were harvested for the determination of root elongation. The remaining plants were continued to grow for 1 h in the same solutions in the presence of $25 \text{ }\mu\text{M}$ Al, pH 4.5. After the Al treatment 1-cm root tips were excised for Al analysis.

Measurement of root-elongation rate

Two hours before the treatment was initiated tap roots were marked three centimetres behind the root tip using a fine point permanent marker (Sharpie blue, Stanford) which did not affect root growth during the experimental period. Afterwards, the plants were transferred into a simplified nutrient solution (see above) without or with PEG in the absence or presence of $25 \text{ }\mu\text{M}$ Al. Root elongation was measured after the treatment period using a mm scale.

Collection of root exudates and determination of organic acids in exudates and root apices

To collect root exudates from root apices, plants were pre-treated with 0 or $25 \text{ }\mu\text{M}$ Al in the

absence or presence of 150 g L⁻¹ PEG for 3, 7 and 23 h, then ten plants were bundled in filter paper soaked with nutrient solution. Approximately 1 cm of the main root apex of each plant was immersed into 15 mL of a constantly aerated incubation solution containing 5 mM CaCl₂, 1 mM KCl, 8 μM H₃BO₃, and 0 or 40 μM AlCl₃, pH 4.5. During this treatment process, the basal part of the root system was constantly moistened with incubation solution (see above) to prevent dryness but avoiding dripping into the columns. After 2 h, the incubation solution containing the root exudates were immediately frozen at -20 °C. After thawing, the incubation solution was passed through 5 g of a cation-exchange resin (AG50W-X8 with a 75 – 150 μm mesh) in 20 mL poly-prep columns with a 200 – 400 μm mesh filter at the bottom of the column, at a flow rate of 1 mL min⁻¹. The resulting solution containing the organic acids (OA) was concentrated to dryness in a rotary vacuum evaporator (RCT 10-22T, Jouan, Saint-Herblain, France). The residue from each sample was re-dissolved in 500 μL (10 mM) perchloric acid, sonicated for 15 min, filled into micro filtration tubes with a membrane pore size of 0.45 μm (GHP Nanosep MF Centrifugal Device, Pall Life Sciences, Ann Arbor, USA), and filtered by centrifugation at 20,000 g for 25 sec. The filtered samples were immediately used for measurement or frozen.

The OA content of root tips was determined by the modified method of de la Fuente *et al.* (1997). Plants were treated with 0 or 25 μM Al in the absence or presence of 150 g L⁻¹ PEG for 4, 8 and 24 h, then the root tips (1-cm) were excised and frozen immediately in liquid nitrogen. Before thawing, 400 μL of cold 70 % (v/v) ethanol was added to the samples which were then homogenized in a micro-homogenizer (MM200 Retsch, Haan, Germany) for 3 min at 20 cycles sec⁻¹. OAs were extracted at 75 °C for 1 h with intermittent shaking on a vortex every 15 min. Thereafter, the samples were centrifuged at 23,000 g for 10 min and the supernatant was transferred into a new Eppendorf tube. The supernatant was concentrated to dryness in a rotary vacuum evaporator. The concentrated residue from each sample was re-dissolved in 200 μL 10 mM perchloric acid, sonicated for 15 min, transferred to centrifugal micro filtration tubes with a membrane pore size of 0.45 μm, and centrifuged at a speed of 20,000 g for 25 sec. The samples were immediately used for measurement or frozen.

The concentrations of OAs in the root exudates as well as in the extracts of root tissue were measured by isocratic High Pressure Liquid Chromatography (HPLC, Kroma System 3000, Kontron Instruments, Munich, Germany). The OAs were detected through a 20 μL loop-injector (Auto-sampler 360) of the HPLC, separating different OAs on an Animex

HPX-87H (300 x 7.8 mm) column (BioRad, Laboratories, Richmond, California, USA), supplemented with a cation H⁺ micro-guard cartridge, using 10 mM perchloric acid as eluent at a flow rate of 0.5 mL per minute, at a constant temperature of 35 °C (Oven 480), and with a pressure of 7.4 kPa. Measurements were performed at $\lambda = 214$ nm (UV Detector 320).

Freeze-fracture scanning electron microscopy

The effect of PEG on the structure of the root tips was studied at the Research Centre of Bayer CropSciences at Monheim, Rhein, Germany, in cooperation with P. Baur and S. Teitscheid. After treating the plant with PEG 6000 and PEG1000 (-0.60 MPa OP) for 4 h, root tips (1 - 5 mm from the root apex) were excised and placed onto a specimen holder, then shock frozen with liquid nitrogen. Frozen specimens were transferred to a pre-cooled (-150 °C) specimen stage in a vacuum-cryo-shuttle into the preparation-chamber, fractured with knife and etched (sublimated) in the specimen-chamber for 10 min at -100 °C under 10^{-4} mbar to remove surface ice. The structure of root-tip cross-sections was examined using a scanning electron microscope (SEM, JSM-5600 LV, Jeol, Tokyo, Japan) after gold sputtering.

Isolation of cell-wall material

After pre-treating with PEG (0 – 200 g L⁻¹) for 24 h, thirty root tips of 1-cm length were excised and transferred to 1 mL of 96% ethanol (method A) or immediately frozen in liquid nitrogen and then ground to fine powder with mortar and pestle in liquid nitrogen before 1 ml of 96% ethanol was added (method B). Cell-wall material was prepared as alcohol-insoluble residue after repeated washing with ethanol, modified after Schmohl and Horst (2000). Root samples were thoroughly homogenized in ethanol using a mixer mill at a 30 cycles s⁻¹ for 2 min. The homogenization was repeated two times. Then the samples were centrifuged at 23,000 g for 15 min and the supernatant was discarded. One millilitre of 96% ethanol was added and the pellet was re-suspended. The washing procedure was repeated twice. The remaining CW material was dried using a centrifugal evaporator (RC10-22T, Jouan SA, France), weighed, and stored at 4 °C for further use.

Determination of pectin and its degree of methylation

The dried cell-wall material isolated from 1-cm root tips was weighed, hydrolysed according to Ahmed and Labavitch (1977) extending the incubation time to 10 min in

concentrated H₂SO₄ and 2 h after each step of water addition. The uronic acid content was determined colorimetrically according to Blumenkrantz and Asboe-Hansen (1973) using a microplate spectrophotometer (μ QuantTM; Bio-Tek Instruments, Winooski, VT, USA). Galacturonic acid was used as a calibration standard; thus the root pectin content was expressed as galacturonic acid equivalent (GaE).

For the determination of the degree of methylation (DM), the cell-wall material from root apices was prepared in the same way as for pectin determination. Methanol was released from the cell-wall material by saponification according to Fry (1988), modified after Wojciechowski and Fall (1996). After addition of 2 units of alcohol oxidase (EC 1.1.3.13 from *Picchia pastoris*; Sigma, Deisenhofen, Germany) the complex of formaldehyde with Fluoral-P (15 mg mL⁻¹) (Molecular Probes, Leiden, The Netherlands) was measured fluorometrically (excitation λ = 405 nm, emission λ = 503 nm). The degree of methylation (%) was calculated as the molar ratio of methanol/uronic acid $\times 100$.

Cell-wall binding-capacity and uptake of Al³⁺, La³⁺, Sr²⁺, Rb²⁺ in 1-cm root apices

The isolated cell-wall material from 30 root tips (approximately 3 mg) was incubated for 30 min in 1 mL of a solution (pH 4.3) containing 300 μ M AlCl₃ or 300 μ M LaCl₃, 450 μ M SrCl₂ or 900 μ M RbCl without or with 150 g L⁻¹ PEG. Then the suspension was centrifuged at 23,000 g for 10 min. The supernatant was discarded. The pellet was re-suspended in one ml of ultra-pure deionized water and centrifuged again. The procedure was repeated twice. Then the residues were prepared for Al, La, Sr and Rb determination.

To study the effect of PEG on the accumulation of La³⁺, Sr²⁺ and Rb⁺ in the root apices, intact plants were pre-treated with the simplified nutrient solution and 0 or 50, 100, 150, 200 g L⁻¹ PEG (pH 4.5) for 8 h. Then the plants were treated with 25 μ M AlCl₃, 5 μ M LaCl₃, 2.5 mM SrCl₂, or 0.5 mM RbCl minus or plus 150 g L⁻¹ PEG in the same nutrient solution for 1 h, pH 4.5.

Determination of Al, La, Sr, and Rb

For the determination of Al, La, Sr, and Rb, 1-cm root tips or cell-wall material were digested in 500 μ L ultra-pure HNO₃ (65%, v/v) by overnight shaking on a rotary shaker. The digestion was completed by heating the samples in a water bath at 80 °C for 20 min. Then 1.5 mL ultra-pure deionised water was added after cooling the samples in an ice-water bath. Aluminium was measured with a Unicam 939 QZ graphite furnace atomic

absorption spectrophotometer (GFAAS; Analytical Technologies Inc., Cambridge, UK) at a wavelength of 308.2 nm after appropriate dilution, and an injection volume of 20 μL . La, Sr, and Rb were measured by inductively coupled plasma mass spectroscopy (ICP-MS) (7500cx, Agilent Technology, Santa Clara, California, USA) after appropriate dilution.

Statistics analysis

A completely randomized design was used, with four to twelve replicates in each experiment. Statistical analysis was carried out using SAS 9.2. Means were compared using t or Tukey test depending on the number of treatments being compared. *, **, *** and ns denote significant differences at $P < 0.05$, 0.01, 0.001, and not significant, respectively.

Results

Four common bean genotypes differing in Al resistance were selected to investigate the relationship between Al toxicity and drought stress. The genotypes responded to Al treatment as previously reported, with Quimbaya as most Al-resistant and VAX 1 as most Al-sensitive (Fig. 1A; Rangel et al., 2005). PEG treatment led to severe osmotic stress and thus inhibition of root growth. Although the comparison of means did not show significant differences between genotypes in response to PEG, the ANOVA showed a highly significant genotype*Al interaction with genotype Quimbaya showing the highest and BAT 477 the lowest root growth in presence of PEG. Combined Al and PEG stress did not lead to further root-growth inhibition. On the contrary, PEG in addition to Al stress enhanced root growth compared to Al stress alone (highly significant PEG*Al interaction) particularly in genotype VAX 1 (highly significant genotype*PEG*Al interaction). The lack of Al-induced inhibition of root elongation and even the positive effect of PEG on root growth in presence of Al can be explained by a strongly reduced Al accumulation in the root tips (Fig. 1B).

Since among the tested genotypes the PEG-improved root growth in presence of Al was most marked in VAX 1, the study was continued with this genotype only. The lower Al accumulation in the root apices of PEG-stressed plants could be due to an enhanced synthesis and exudation of organic acids because citrate exudation has been reported as one of the most important mechanisms of Al resistance in common bean. Therefore, the contents and the exudation rates of organic acids were determined after 4, 8, and 24 h of PEG and Al treatment in order to take into account the adaptations to Al (Rangel et al., 2007) and PEG (data not shown) over the treatment period.

Whereas Al treatment decreased the contents of most organic acids with increasing treatment duration, PEG treatment/drought stress strongly enhanced OA contents in the root tissue, particularly of citrate and malate independent of the Al treatment (Fig. 2). Since organic acids could not be analyzed in the presence of PEG and PEG could not be satisfactorily separated from the solution, organic acid anion exudation had to be determined during a two hour period without PEG (but with Al) supply after the corresponding PEG pre-treatment. After removing of PEG from the treatment solution, the amount of organic acid in 1-cm root apical tissues did not change during the subsequent 2 h exudate collection-period and confirmed the organic acid contents (data not shown). Only malate, but not citrate exudation was affected by PEG treatment (Fig. 3). On the other

hand, AI significantly enhanced citrate exudation independent of the PEG pre-treatment up to 9 h treatment (Fig. 3).

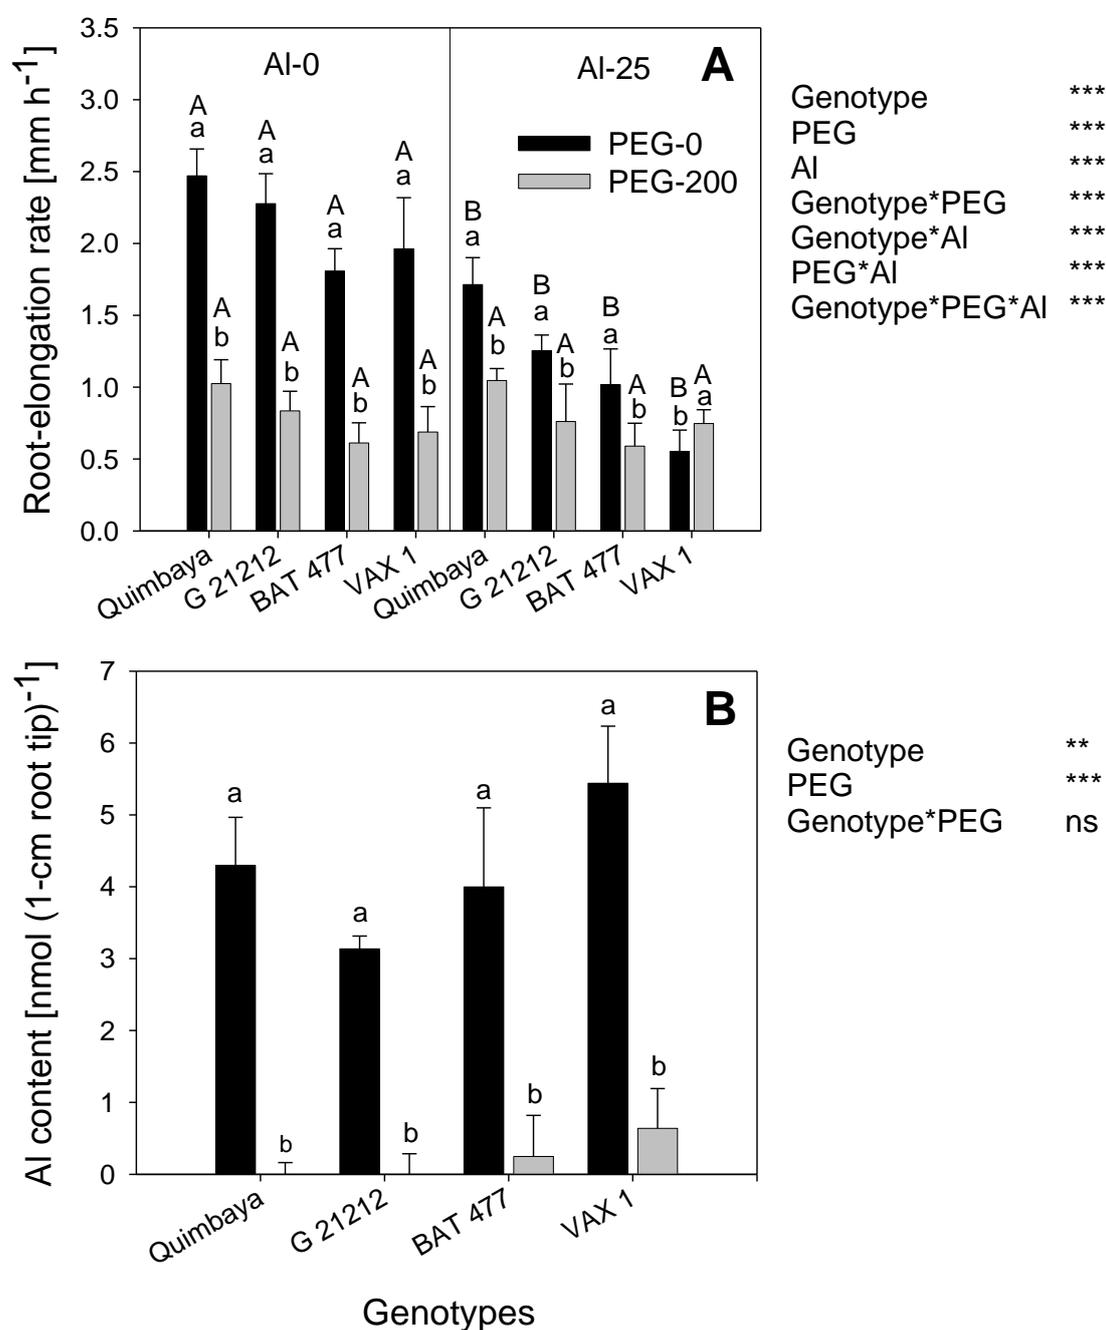

Figure 1 Root-elongation rate (A) and Al content of 1-cm root tips (B) of four common bean genotypes under osmotic (200 g L^{-1} PEG) and Al stress ($25 \mu\text{M}$ Al). Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl , and $8 \mu\text{M H}_3\text{BO}_3$ for 48 h for acclimation and pH adaptation, then treated without or with $25 \mu\text{M}$ Al in the absence or presence of 200 g L^{-1} PEG in the simplified nutrient solution for 24 h, pH 4.5. Bars represent means \pm SD, $n = 12$ for (A) and $n = 4$ for (B). Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of PEG treatments within Al supplies and comparison of Al treatments within PEG supplies, respectively. For the ANOVA, **, *** denote significant differences at $P < 0.01$, $P < 0.001$, respectively; ns = not significant.

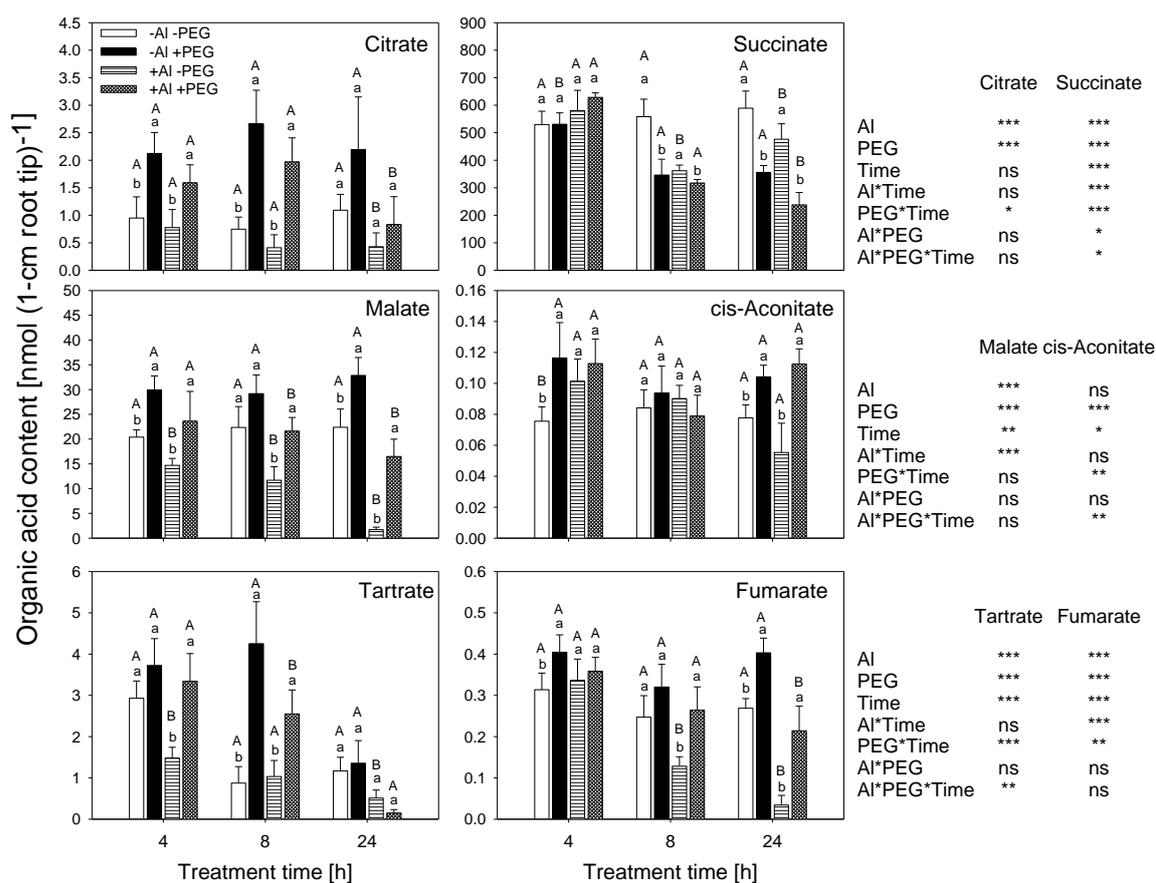

Figure 2 Organic acid contents in 1-cm apical roots of common bean genotype VAX 1 (Al-sensitive) affected by osmotic stress and Al supply. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, then treated without or with Al (25 μM) in the absence or presence of PEG (150 g L^{-1}) in the simplified nutrient solution for 4, 8 and 24 h, pH 4.5. Bars represent means \pm SD, $n = 4$. Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of PEG treatments within Al supplies and comparison of Al treatments within PEG supplies, respectively. For the ANOVA, *, **, *** denote significant differences at $P < 0.05$, $P < 0.01$, $P < 0.001$, respectively; ns = not significant (F test).

Another reason for the impeded Al accumulation in the root apices could be a lower negativity of the CWs formed in the presence of PEG. The cell-wall pectin-content and its degree of methylation determine the Al binding capacity of the root cell-wall (Schmohl and Horst, 2000). PEG treatment reduced total CW pectin content but also decreased the degree of methylation of pectin in 1-cm root tips. Thus the content of unmethylated pectin representing the negativity of the CWs remained unaffected by the PEG treatment (Fig. 4).

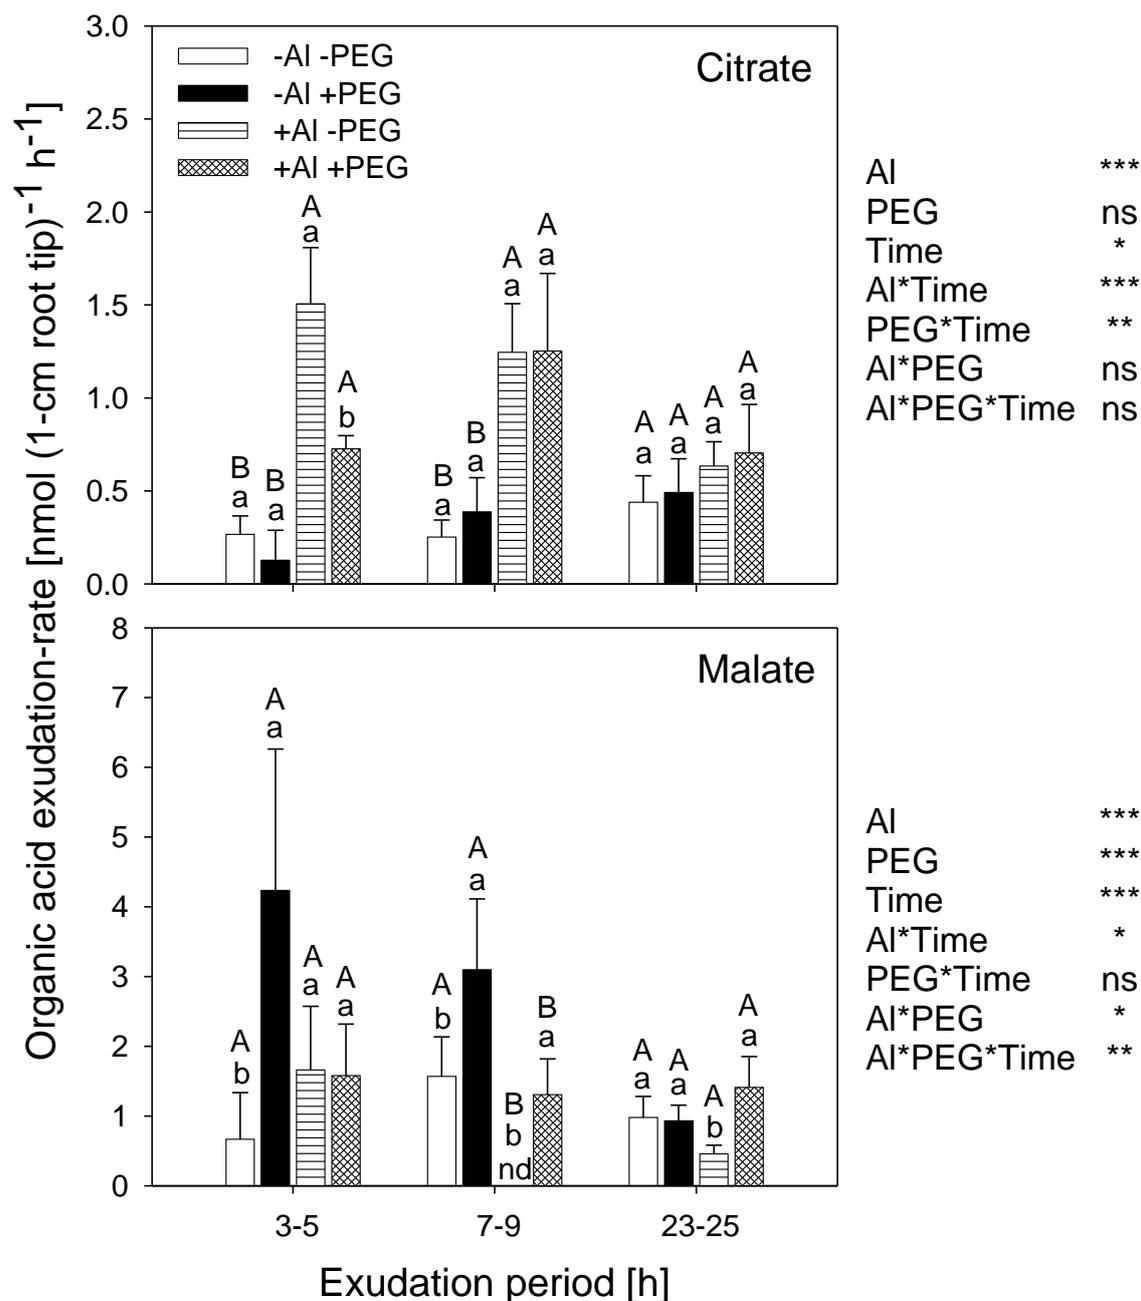

Figure 3 Effect of PEG and Al treatment on organic acid exudation from 1-cm root apices of Al-sensitive common bean genotype (VAX 1). Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation and then treated without or with Al (25 μM) in the absence or presence of PEG (150 g L^{-1}) for 3, 7 and 23 h. Thereafter, the roots of 10 plants were bundled and the root tips (1 cm) were incubated in 15 mL of Al (0, 40 μM) treatment solution containing the above simplified nutrient solution without PEG for 2 h. Bars represent means \pm SD, $n = 4$. Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of PEG treatments within Al supplies and comparison of Al treatments within PEG supplies, respectively. For the ANOVA, *, **, *** denote significant differences at $P < 0.05$, $P < 0.01$, $P < 0.001$, respectively; ns = not significant (F test). nd = not detected.

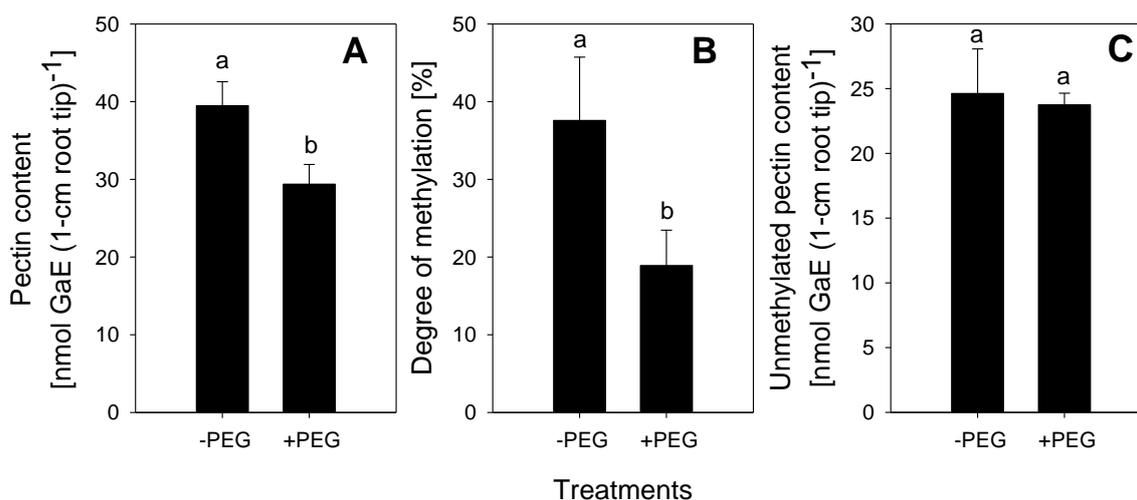

Figure 4 Total cell-wall pectin-content (A), its degree of methylation (B) and unmethylated pectin content (C) in 1-cm root tips of Al-sensitive common bean genotype (VAX 1). Plants were pre-treated without or with 150 g L⁻¹ PEG in a simplified solution (pH 4.5) containing 5 mM CaCl₂, 1 mM KCl and 8 μM H₃BO₃ for 24 h, then 30 root tips (1-cm) were harvested and cell-wall material was isolated according to Method A described in materials and methods for determination of pectin content and degree of methylation. Bars represent means ±SD, n = 4. Means with the same letters are not significantly different at *P* < 0.05 (t test).

In order to differentiate between a direct effect of PEG accumulation on/in the root and of PEG-induced osmotic stress on Al accumulation in the roots, the roots were enclosed in a DMT, which has a molecular weight cut off (MWCO) of 3,500 Dalton and does not allow PEG 6000 to cross the membrane. Thus, the direct contact of PEG with the root was prevented while maintaining the osmotic stress. Higher PEG and Al concentrations were used with rather than without DMT according to preliminary experiments to compensate for impeded PEG and Al diffusion through the DMT (data not shown). As shown above, presence of PEG during the Al treatment period of 1 h reduced the Al accumulation in the root tips to low levels even in plants not exposed to PEG during the 8 h pre-treatment period (-/+ PEG) (Fig. 5A). Discontinuing the PEG treatment during the 1 h Al treatment period after 8 h PEG pre-treatment (+/- PEG) completely restored the Al accumulation capacity of the root apices. This recovery is a very rapid process since as early as 15 min after interrupting the PEG treatment the difference in Al accumulation between PEG-treated and untreated plants disappeared (Fig. 5C). When the roots were protected against direct contact with PEG using DMT (Fig. 5B) Al accumulation by the roots was similarly reduced when osmotic stress was applied during the 1 h Al uptake period. However, when the osmotic stress was discontinued during the Al uptake period (+/- PEG) the Al uptake capacity was not fully restored as to the level observed without DMT. This

suggests a slower recovery from osmotic stress in the dialysis tubes.

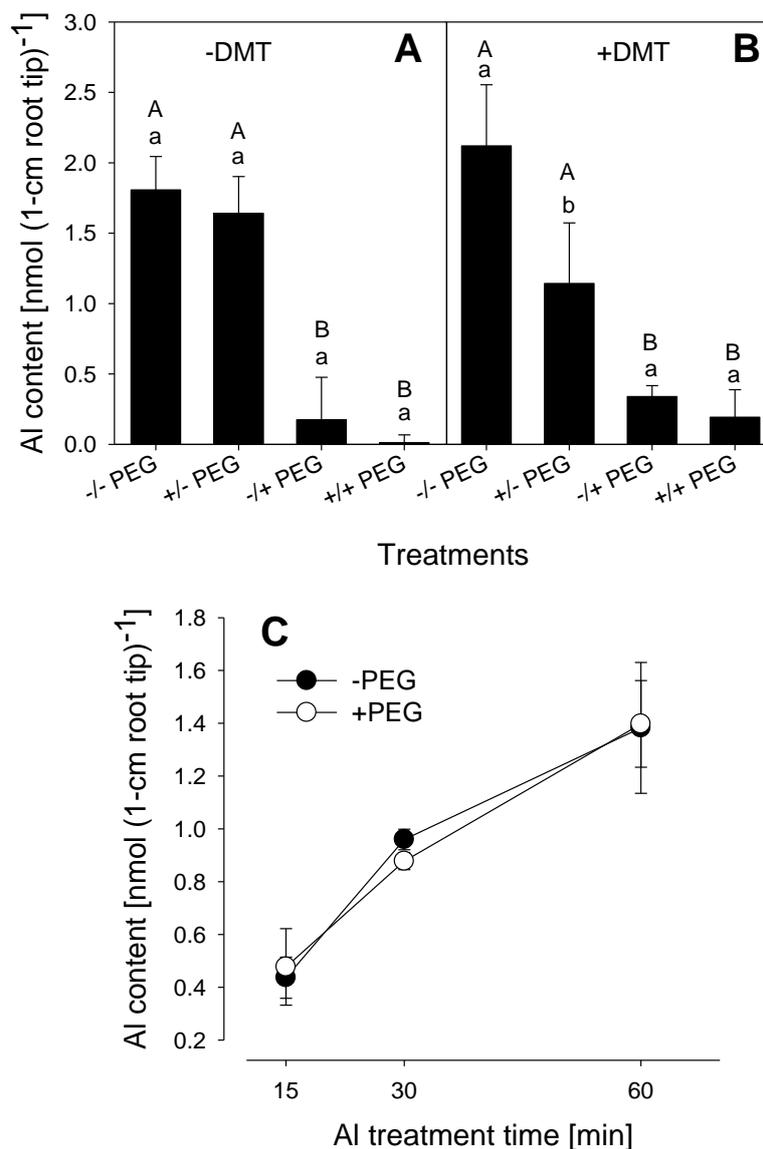

Figure 5 Al content in 1-cm root tips of Al-sensitive common bean genotype (VAX 1). (A) Without dialysis membrane tubes (DMT); plants were pre-treated without or with 150 g L⁻¹ PEG solution for 8 h, and then treated with 25 μM Al in the absence or presence of 150 g L⁻¹ PEG solution for 1 h. (B) With DMT; plants were pre-treated without or with 200 g L⁻¹ PEG for 8 h, then treated with 100 μM Al in the absence or presence of 200 g L⁻¹ PEG solution for 1 h. (C) Without DMT; plants were pre-treated without or with 150 g L⁻¹ PEG solution for 8 h, and then treated with 25 μM Al solution for 15, 30 and 60 min. The background solution of the above treatment solution was the simplified solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃, pH 4.5. -/- PEG: without PEG during pre-treatment and Al treatment; +/- PEG: with PEG during pre-treatment, without PEG during Al treatment; -/+ PEG: without PEG during pre-treatment, with PEG during Al treatment; +/+ PEG: with PEG during pre-treatment and Al treatment. Bars represent means ± SD, n = 4. Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of PEG pre-treatments within PEG re-treatments and comparison of PEG re-treatments within PEG pre-treatments, respectively.

Since the presence and thus penetration of the DMT by LMW PEG in PEG 6000 cannot be excluded we studied the OP as an indirect measure of the presence of LMW PEG in the solution passing through the DMT in a model experiment in which the PEG 6000-filled DMT was incubated for 4 hours. There was only a slight decrease of the OP which was only significant in the ten times concentrated incubation solution (Fig. S1). Even then the OP did not decrease beyond -0.06 MPa which did not affect root growth (Fig. 6A). This suggests that there is only a low amount of LMW PEG in the PEG 6000 product used for our experiments.

To clarify how LMW PEG affect Al accumulation in the root apex, the effect of PEG 6000, PEG 3000, and PEG 1000 on Al contents in the root tips was compared at the same OPs corresponding to PEG 6000 concentrations of 0, 50, 100, 150 g L⁻¹. The root elongation rate was decreased with decreasing OP independent of the molecular weight of the PEG (Fig. 6A). However, PEG 6000 reduced the Al contents of the root tips much more efficiently than PEG 3000 and particularly PEG 1000 (Fig. 6B).

The effect of different molecular weight PEG on the root-tip structure has been studied using freeze-fracture electron microscopy. The resolution of the technique did not allow to draw any conclusion about the cell wall structure. However, the root cross-sections shown in Fig. S2 clearly showed that in spite of comparable osmotic stress induced by the different molecular weight PEG (compare Fig. 6A) the effects on the root structure were different. In roots exposed to PEG 6000 (Fig. S2C, F) the epidermis and the outer cortical cell layers were very closely packed and nearly all intercellular spaces disappeared. In contrast, PEG 1000 (Fig. S2B, E) did hardly affect the intercellular space compared to the control (Fig. S2A, D) indicating that in addition to osmotic stress PEG 6000 dehydrates the root apoplast more than PEG 1000.

The specificity of the PEG 6000 effect on Al uptake into the root apex was evaluated using La, Sr and Rb uptake for comparison (Fig. 7). PEG pre-treatment did not affect La uptake, while PEG applied together with La slightly but significantly decreased La accumulation (Fig. 7A). In contrast, neither PEG pre-treatment (+/- PEG) nor re-supply of PEG (-/+ PEG) during the Sr uptake period affected Sr (as a tracer of Ca) accumulation in the root apices (Fig. 7B). However Rb (as a tracer of K) accumulation was reduced by PEG pre-treatment (+/- PEG) and PEG application (-/+ PEG) during the Rb exposure period (Fig. 7C), which might be explained by a significant increase of the K content in the root tips (from 212 to 342 nmol root-tip⁻¹, data not shown) caused by osmotic stress.

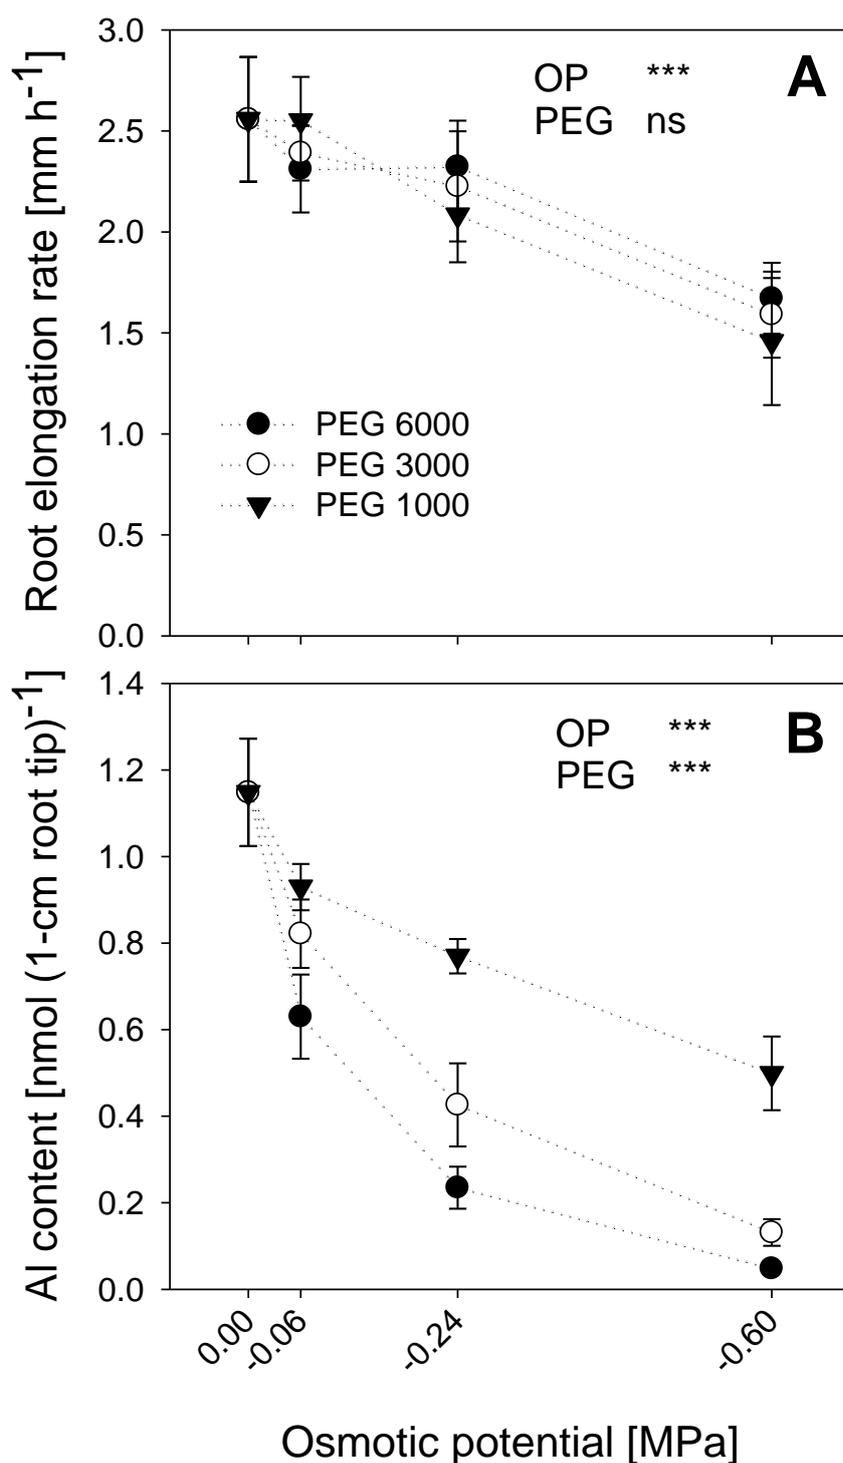

Figure 6 Effect of different molecular weight PEGs on root growth and Al accumulation in root tips of Al-sensitive common bean genotype (VAX 1). (A) Plants were pre-treated with different molecular weight PEGs at different osmotic potentials for 8 h. (B) Plants were pre-treated with different molecular weight PEGs at different osmotic potentials for 8 h, and then treated with $25 \mu\text{M}$ Al for 1 h in the presence of different molecular weight PEGs for 1 h. The background solution of the above treatment solution was the simplified solution containing 5 mM CaCl_2 , 1 mM KCl , and $8 \mu\text{M H}_3\text{BO}_3$, pH 4.5. Bars represent means \pm SD, $n = 4$. For the ANOVA, *** denote significant differences at $P < 0.001$; ns = not significant (F test).

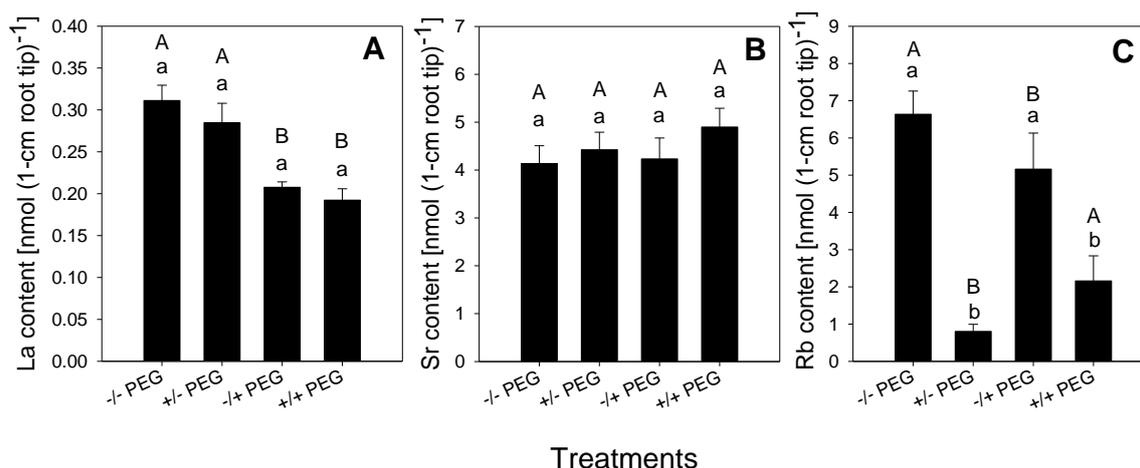

Figure 7 Effect of PEG pre-treatment/treatment on La (A), Sr (B) and Rb (C) accumulation of 1-cm root tips in Al-sensitive common bean genotype (VAX 1). Plants were pre-treated without (- PEG) or with 150 g L⁻¹ PEG (+ PEG) in a simplified solution (pH 4.5) containing 5 mM CaCl₂, 1 mM KCl and 8 μM H₃BO₃ for 8 h. Then the plants were supplied with 5 μM LaCl₃, 2.5 mM SrCl₂ or 0.5 mM RbCl in absence (-/-, +/- PEG) or presence of 150 g L⁻¹ PEG (-/+, +/+ PEG) in the same nutrient solution as described above for 1 h. Bars represent means ± SD, n = 4. Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of PEG pre-treatments within PEG re-treatments and comparison of PEG re-treatments within PEG pre-treatments, respectively.

Cell-wall material isolated from 1-cm root apices of plants treated without or with PEG (150 g L⁻¹) was exposed to Al, La, Sr, or Rb for 30 min in the absence or presence of PEG. PEG pre-treatment strongly reduced Al binding to the CWs (Fig. 8A). In contrast to Al, La accumulation was only slightly reduced (Fig. 8B), and Sr and Rb accumulation was not affected by PEG (Fig. 8C, D). Application of PEG only during the Al loading period did not affect the Al-binding properties of the isolated cell-wall material (Fig. 8A). Moreover, the different effects of osmotic stress on Rb accumulation *in vivo* (Fig. 7C) and *in vitro* (Fig. 8D) conditions suggest that the apoplast is not the main binding site of Rb, which may play an important role in the osmotic adjustment of the cytoplasm similar to K (Ogawa and Yamauchi, 2006).

Al accumulation in 1-cm root apices of intact plants (Fig. 9A) and Al binding to the CWs of these root tips (Fig. 9A') decreased with increasing PEG concentration (0 - 150 g L⁻¹) in the treatment solution. A similar decreasing tendency was also observed for La, although the relative change was much lower compared to Al (Fig. 9B, B'). Unlike that of Al and La, Sr uptake/binding was not reduced by PEG treatment (Fig. 9C, C'). A higher concentration of PEG (200 g L⁻¹) did not further reduce Al and La uptake and its binding to the CW of root tips (Fig. 9). A PEG supply of 250 g L⁻¹ was found to be lethal to the plants

since it seriously damaged the root system (data not shown).

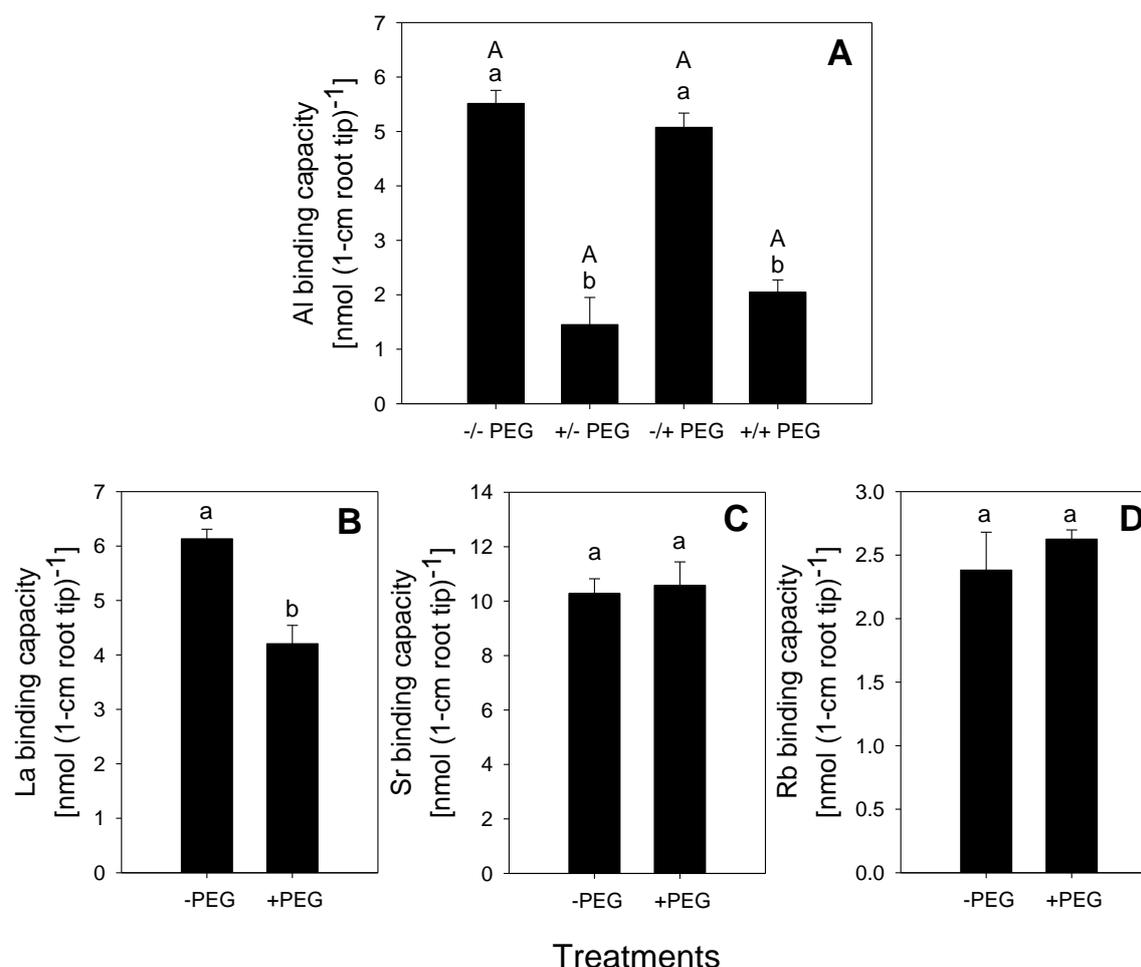

Figure 8 Al^{3+} (A), La^{3+} (B), Sr^{2+} (C) and Rb^+ (D) binding of cell-wall material isolated from of 1-cm root tips of Al-sensitive common bean genotype (VAX 1). Plants were pre-treated without or with 150 g L^{-1} PEG for 24 h in a simplified solution (pH 4.5) containing 5 mM CaCl_2 , 1 mM KCl and $8 \text{ }\mu\text{M H}_3\text{BO}_3$. Then 30 root tips (1-cm) were harvested for each sample and cell-wall material isolated according to Method A described in materials and methods. Then the isolated cell-wall material was treated with $1 \text{ mL } 300 \text{ }\mu\text{M Al}$ minus or plus 150 g L^{-1} PEG, $300 \text{ }\mu\text{M LaCl}_3$, $450 \text{ }\mu\text{M SrCl}_2$, or $900 \text{ }\mu\text{M RbCl}$ for 30 min, pH 4.3. -/- PEG: without PEG during pre-treatment and Al treatment; +/- PEG: with PEG during pre-treatment and without PEG during Al treatment; -/+ PEG: without PEG during pre-treatment and with PEG during Al treatment; +/+ PEG: with PEG during pre-treatment and Al treatment. Bars represent means \pm SD, $n = 4$. Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of PEG pre-treatments within PEG re-treatments and comparison of PEG re-treatments within PEG pre-treatments, respectively.

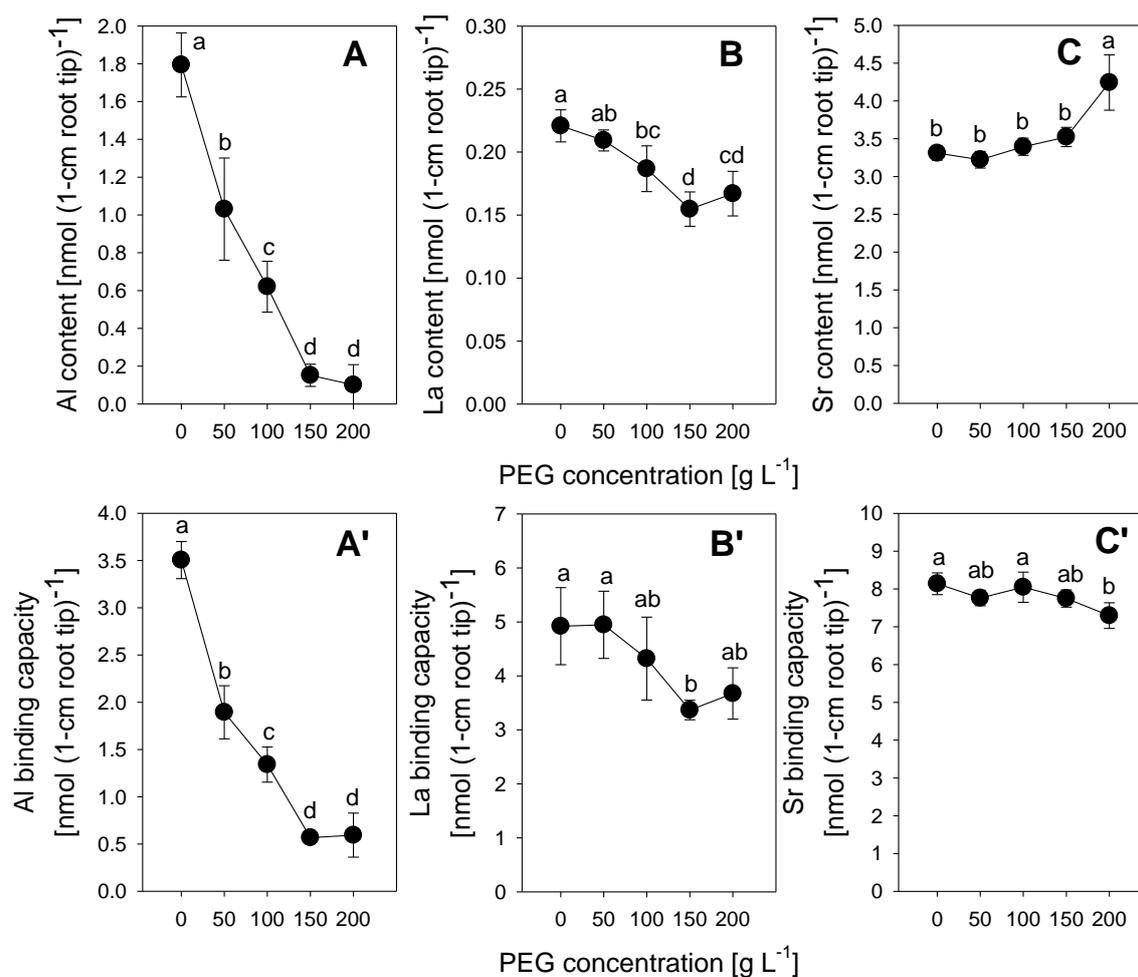

Figure 9 Effect of PEG treatment on Al, La and Sr accumulation of 1-cm root tips (A, B, C) and binding of cell-wall material isolated from 1-cm root tips (A', B', C') of Al-sensitive common bean genotype (VAX 1). (A, B, C) Plants were pre-treated with PEG (0 - 200 g L⁻¹) for 8 h in a simplified solution (pH 4.5) containing 5 mM CaCl₂, 1 mM KCl and 8 μM H₃BO₃. Then the plants were supplied with 25 μM AlCl₃, 5 μM LaCl₃, or 2.5 mM SrCl₂ in the presence of PEG (0 - 200 g L⁻¹) in the same nutrient solution for 1 h as described above. (A', B', C') Plants were pre-treated with PEG (0 - 200 g L⁻¹) for 24 h in the simplified solution. Then 30 root tips (1-cm) were harvested for each sample and cell-wall material isolated according to Method A described in materials and methods. Then the isolated cell-wall material was treated with 1 mL 300 μM Al, 300 μM LaCl₃, or 450 μM SrCl₂ for 30 min, pH 4.3. Bars represent means ± SD (n = 4). Means with the same letters are not significantly different at $P < 0.05$ (Tukey test).

To elaborate the role of PEG-induced alteration of cell-wall structure on Al binding, a simple physical method (method B) was used to destroy the CW structure by vigorously grinding the root apices with mortar and pestle in liquid nitrogen. PEG pre-treatment resulted in about 70% reduction of Al binding when the CW structure was widely unaltered (method A; Fig. 10). But by destroying the CW structure (method B) Al binding was restored in the PEG pre-treated samples. This indicates that PEG reduces CW porosity and

restricts the access of Al ions to binding sites.

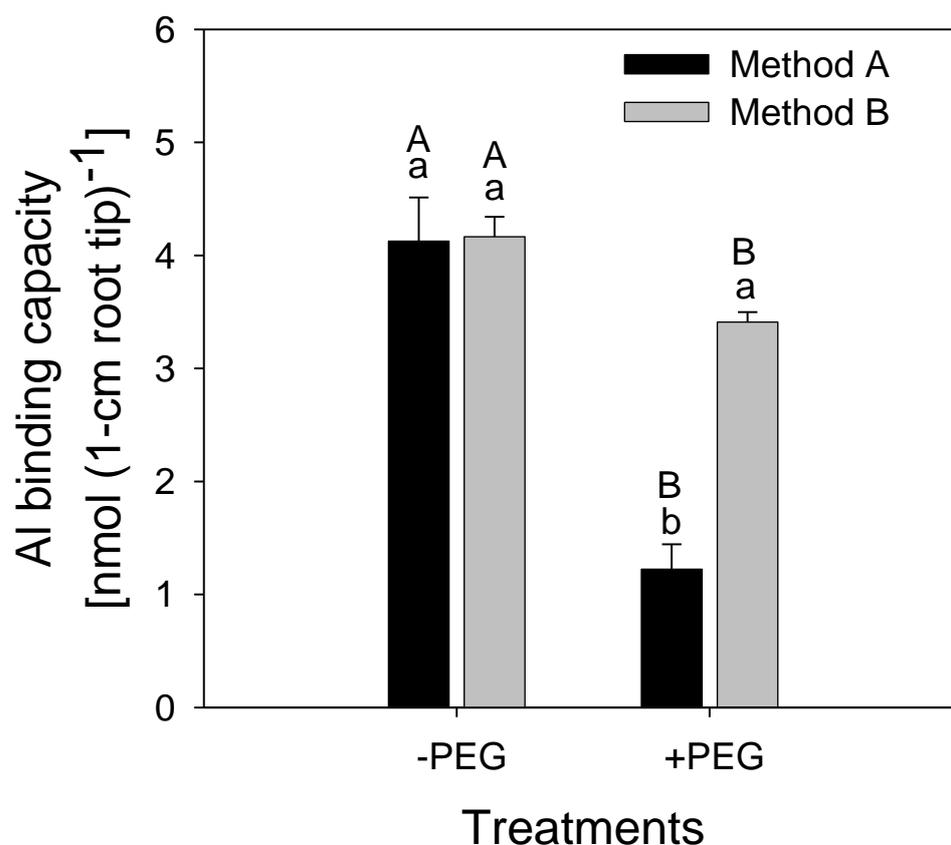

Figure 10 Al³⁺ binding of cell-wall material isolated from 1-cm root tips of Al-sensitive common bean genotype (VAX 1). Plants were pre-treated without or with 150 g L⁻¹ PEG for 24 h in a simplified solution (pH 4.5) containing 5 mM CaCl₂, 1 mM KCl and 8 μM H₃BO₃. Then, thirty root tips (1-cm) were harvested and cell-wall material was isolated according to method A or method B, described in materials and methods. Then the isolated fine cell-wall powder was treated with 1 ml 300 μM Al for 30 min, pH 4.3. Bars represent means ± SD, n = 4. Means with the same small letter and capital letter are not significantly different at $P < 0.05$ (t test) for the comparison of the method of CW isolation within PEG pre-treatments and comparison of PEG pre-treatments within the method of CW isolation, respectively.

Discussion

Generally, there is a positive relationship between Al-induced short-term inhibition of root elongation and Al accumulation in the root-tip apoplast of common bean (Rangel et al., 2009) indicating that Al resistance involves exclusion of Al from the root-tip apoplast (Horst et al., 2010). In the present study, PEG 6000-induced osmotic stress significantly inhibited Al accumulation in the root tips reaching almost the level of the control (Fig. 1B). Consequently, there was no Al toxicity which is reflected by the lack of any additional Al effect on the root elongation of PEG 6000-stressed plants (Fig. 1A). The possibility that PEG or contaminants associated with the PEG may decrease Al uptake into the root apex by complexing or precipitating Al in the treatment solution can be excluded because PEG application did not affect the mononuclear phytotoxic Al concentration of the treatment solution (data not shown).

Citrate exudation contributes to Al resistance of common bean by excluding Al from the root apex. In the present study, Al stress significantly increased citrate exudation from root apices during the early Al injury period (3 – 9 h), but the exudation was reduced with time (Fig. 3), which is typical for this Al-sensitive genotype VAX 1 (Rangel et al., 2010). The reduction of citrate exudation was related to the decreasing citrate content in the root apex (Fig. 2). These results confirm our previous studies that Al resistance of common bean through citrate exudation requires the maintenance of the cytosolic citrate concentration through up-regulated synthesis and down-regulated degradation (Rangel et al., 2010, Eticha et al., 2010). Abscisic acid (ABA), known as a stress-inducible phytohormone, plays important regulatory roles in the adaptation of root growth to drought and salt stress (Sharp, 2002; Ren et al., 2010). As an early Al-stress signal it may also regulate citrate exudation since exogenous application of ABA increased the activity of citrate synthase (CS) and citrate exudation, thus decreasing Al accumulation in the root apex of soybean (Shen et al., 2004). Therefore, we speculate that drought stress-induced ABA synthesis may directly or indirectly enhance citrate exudation through stimulating citrate production in the root apex which detoxifies Al and contributes to improved root growth under Al stress condition. Under medium-term (4 – 24 h) Al stress, the citrate content in the root apex was enhanced by PEG (osmotic stress) treatment (Fig. 2). However, PEG pre-treatment did not affect citrate exudation from the root apex (Fig. 3), suggesting that osmotic stress did not induce the exclusion of Al from root apices by increasing citrate exudation. Since relieving of the osmotic stress by withdrawing PEG from the solution

rapidly restored the Al accumulation capacity of the root apices (Fig. 5), the contribution of citrate exudation in reducing the Al binding capacity in presence of PEG cannot be unequivocally ruled out.

The apoplast of the root apex has been proposed to be the primary site of Al toxicity (Horst, 1995; Horst et al., 2010). Many reports indicate that Al in the root primarily accumulates in the CW. Rangel et al. (2009) found that about 80% of the total Al in the root of common bean was bound in the CW. Similar findings were reported for soybean (Yang et al., 2009). The density of the negative charge carried by the CW is determined by the degree of methylation (DM) of pectin which thus determines the Al binding capacity of roots (Schmohl et al., 2000; Eticha et al., 2005; Yang et al., 2008). Therefore, reduced Al accumulation in PEG-stressed plants could be due to CW modification. However, in disagreement with salt (NaCl)-induced osmotic stress of our previous studies in maize, which led to increased pectin content in root apices, enhanced Al accumulation, and thus higher Al sensitivity (Horst et al., 1999), our present results showed that PEG-induced osmotic stress did not affect the content of unmethylated pectin in root apices of common bean (Fig. 4). Therefore, the results do not support the assumption that osmotic stress leads to low Al accumulation by decreasing the CW negativity.

The use of PEG in studies on osmotic stress relies on the assumption that this high molecular weight solute cannot enter the symplastic space of the root (see introduction). However, there are several reports clearly showing that PEG may be accumulated in roots and even transported to the shoot (Lawlor, 1970; Janes, 1974; Yaniv and Werker, 1983; Jacomini et al., 1988). This may depend on the plant species, PEG source (contamination by LMW PEG) and concentration, time of exposure and root damage. If PEG accumulates at the root surface or enters the root apoplast it may physically interfere with Al uptake and its binding to the CW. Therefore, in order to clarify the importance of apoplastic PEG or PEG-induced osmotic stress decreased Al accumulation in root tips, the roots were separated from the PEG in solution using DMT which has a molecular weight cut off of 3,500 Dalton. Aluminium accumulation in the root tips grown in DMTs was also strongly reduced by PEG treatment (Fig. 5) suggesting that not the physical presence of PEG 6000 but the PEG 6000-induced osmotic stress was the cause for lower Al accumulation. A possible contribution of LMW PEG present in the PEG 6000 used for the experiments is unlikely because of two lines of evidence: (i) LMW PEG diffusing through the DMT reduced the OP of the equilibrium solution only to an OP value which hardly affected the Al binding of the roots (Fig. S1, Fig. 6B); (ii) PEG 6000 reduced the Al binding of the

roots more than PEG 3000 and particularly PEG 1000 in spite of similar osmotic stress and inhibitory effects on root elongation rate (Fig. 6).

In comparison with La, Sr, and Rb, the strong reduction of cation accumulation in the root apex by osmotic stress appears to be specific to Al. Osmotic stress had only a much smaller, yet, significant effect on La accumulation (Fig. 7, Fig. 9). In contrast, neither PEG pre-treatment nor re-supply of PEG during the Sr uptake period affected Sr accumulation in the root apices (Fig. 7B). Rubidium accumulation was reduced by PEG pre-treatment and PEG application during the Rb exposure period (Fig. 7C). The reduction of Rb accumulation was only found under *in vivo* conditions. Binding of Rb to the isolated CW of root apices *in vitro* was not affected by PEG pre-treatment (Fig. 8D). This suggests that the apoplast is not the main binding sites of Rb, which may play an important role in the osmotic adjustment of the cytoplasm similar to K (Premachandra et al., 1995; Ogawa and Yamauchi, 2006).

The specificity of cation accumulation might be related to the hydrated ionic radius of the cations: Al^{3+} (0.475 nm) > La^{3+} (0.452 nm) > Sr^{2+} (0.412 nm) = Ca^{2+} (0.412 nm) > K^{+} (0.331 nm) > Rb^{+} (0.329 nm) (Nightingale, 1959). Since the pore size of the CW plays an important role in apoplastic transport of water, ions, metabolites and proteins (Carpita et al., 1979; Brett and Waldron, 1996; Cosgrove, 2005), the differences between the ions in Al accumulation of the PEG-exposed root apices may suggest that PEG (osmotic stress) affects CW porosity. This assumption is supported by the fact that a similar reduction in accumulation specific for Al could also be observed in cell walls isolated from PEG-treated root tips (Fig. 8). Microscopic evaluation showed that the CW material was fairly intact (not shown) indicating that the CW porosity was not disrupted. After physically destroying the structure of the CW, Al binding to the CW was almost restored (Fig. 10).

The CW porosity is reported to be largely controlled by the pectin matrix (Baron-Epel et al., 1988). Schmohl and Horst (2000) suggested that the cross-linking of pectins by Al reduces the permeability of the CW for macromolecules such as proteins by reducing the CW porosity. McKenna et al. (2010) showed that Al and other metals reduced the hydraulic conductivity of bacterial cellulose–pectin composites, used as plant cell-wall analogues to about 30% of the initial flow rate. SEM revealed changes in the ultrastructure of the composites suggesting that metal binding decreased the hydraulic conductivity through changes in pectin porosity.

Pectin can form hydrated gels that push microfibrils apart, easing their sideways slippage

during cell growth, while also locking them in place when growth ceases (Baron-Epel et al., 1988; Fleischer et al., 1999; Cosgrove, 2005). For example, Jarvis (1992) indicated that pectin may act as a hydrophilic filler to prevent aggregation and collapse of the cellulose network. Therefore, the reduction of pectin in the CW of root apices under osmotic stress (Fig. 4) may change the structure of the CW, consequently resulting in a rearrangement of wall polymers and affecting the porosity.

Generally, the pore diameter of the plant CW is in the range of 3.5 - 5.5 nm, which mainly depends on CW structure, hydrophobicity, CW chemical composition and physical properties (Carpita et al., 1979; Chesson et al., 1997). Thus any change of these factors may result in subsequent alteration of porosity. For example, Bauchot et al. (1999) reported that low temperature decreased the pore size of the CW of kiwifruit by modifying CW composition. Addition of boric acid to growing borate-deficient suspension-cultured *Chenopodium album* L. cells rapidly decreased the pore size of the CW by the formation of a borate ester cross-linked pectic network in the primary walls (Fleischer et al., 1999). However, although it is reported that plant cells interact with their environment through the porous network of the CW (Carpita et al., 1979), and water stress can induce changes in CW composition and CW properties of roots (Iraki et al., 1989a, b; Wakabayashi et al., 1997; Leucci et al., 2008), to our knowledge, there is no report addressing the effect of drought stress on CW porosity.

Water is the most abundant component of the CW making up about two thirds of the wall mass in growing tissues. This water is located mainly in the matrix ($\approx 75 - 80\%$ water), which suggests that the matrix has properties of a relatively dense hydro-gel (Cosgrove, 1997). This visco-elastic nature of the plant CW allows it to respond to stresses and limitations imposed upon it (Moore et al., 2008). Loss of water from the wall matrix can result in serious disruption to polymer organization. One obvious effect is that polymers usually well separated in the hydrated wall are brought in close proximity to each other, thus causing polymer adhesion or cross-linking under water stress. A model illustrating the effect of water loss on CW polymer organization was presented by Moore et al. (2008).

The extent of loss of water from the apoplast and consequently shrinkage of the root structure appeared to be dependent of the molecular size of the applied PEG: PEG 6000 > PEG 3000 >> PEG 1000 (Fig. S2). The difference between the PEG sources at the same OP of -0.60 MPa might be related to the penetration of the PEG molecules into the root

apoplast: the higher the hydrodynamic radius the better the exclusion from the apoplast and consequently the dehydration of the apoplast. The estimated hydrodynamic radii of PEG 6000, 3000, and 1000 are 2.7, 1.6, and 0.89 nm, respectively (Kuga, 1981).

Also, the rapid recovery of Al accumulation in the living root apex after transfer of the roots into PEG-free solution (Fig. 5C) suggests that the water content of the apoplast is a decisive factor for PEG-induced alteration of CW porosity. However, the CW extension of living cells must involve biochemical (enzymatic) cleavage of load-bearing cross-linkages between wall polymers. Since the restoration of the Al accumulation capacity of the cell walls after the cessation of the PEG stress could only be observed in living root apices (Fig. 5) but not in ethanol-insoluble CW material isolated from root apices pre-treated with PEG (Fig. 8A), a role of enzymes mediating the inhibition of Al accumulation has to be postulated. Several CW proteins/enzymes are believed to play important roles in modifying the wall network and thus, possibly, the wall's ability to extend, such as expansin, xyloglucan endotransglycosylase (XET), glucanase (Wu and Cosgrove, 2000). Therefore, it is speculated that some proteins related to the modification of the CW structure are involved in the PEG 6000 (osmotic stress)-induced alteration of CW porosity. This needs to be substantiated through further physiological and molecular studies.

In conclusion, the observed results provide circumstantial evidence that the osmotic stress-inhibited Al accumulation in root apices and thus reduced Al-induced inhibition of root elongation in the Al-sensitive common bean genotype VAX 1 is related to the alteration of CW porosity resulting from PEG 6000-induced dehydration of the root apoplast.

Abstract

Aluminium (Al) toxicity and drought are two major stress factors limiting common bean (*Phaseolus vulgaris* L.) production on tropical acid soils. Polyethylene glycol (PEG) treatment reduced Al uptake and Al toxicity. The effect of PEG 6000-induced osmotic stress (OS) on the expression of genes was studied using SuperSAGE combined with next generation sequencing and quantitative RT-PCR (qRT-PCR) for selected genes. Less Al stress in PEG-treated roots was confirmed by decreased Al-induced up-regulation of *MATE* and *ACCO* genes. Withdrawing PEG from the Al treatment solution restored the Al accumulation and reversed the *MATE* and *ACCO* genes expression to the level of the treatment with Al alone. Using SuperSAGE, we identified 611 up- and 728 down-regulated genes in PEG-treated root tips, and the results were confirmed by qRT-PCR using 46 differentially expressed genes. Among the 12 genes studied in more detail, *XTHa*, *BEG* (down-regulated by PEG) and *HRGP*, *bZIP*, *MYB* and *P5CS* (up-regulated by PEG) recovered completely within two hours after removal of PEG stress. The results suggest that genes related to CW assembling and modification such as *XTHs*, *BEG* and *HRGP* play important roles in PEG-induced decrease of CW porosity leading to reduced Al accumulation in root tips.

Key words: aluminum, cell wall, common bean, drought, osmotic stress, porosity, qRT-PCR, SuperSAG

Introduction

Common bean (*Phaseolus vulgaris* L.) is the major food legume for human nutrition in the world, and a major source of calories and protein particularly in many Latin American and African countries where middle and low income families are often unable to produce, or afford sufficient animal protein (Graham, 1978; Rao, 2001). However, in these tropical countries, the production of common bean is often limited by the adverse acidic soil conditions, particularly with aluminium (Al), proton, and manganese toxicity together with nutrient deficiencies and seasonal dry spells (Graham and Ranalli, 1997; Thung and Rao, 1999; Yang et al., 2010).

Common bean is generally less adapted to acid soil environments and is also a drought-sensitive crop (Rao, 2001; Beebe et al., 2008). The crop yield on acid soils is mainly limited by Al toxicity. Al resistance in common bean is attributed to the release of citrate by the root apex (Rangel et al., 2010). Generally, in citrate-releasing plant species, the multidrug and toxin extrusion (MATE) family protein, as an Al-activated citrate transporter, was suggested to be responsible for Al resistance. For example, in sorghum (*Sorghum bicolor*), *SbMATE* was expressed only in the root tips of the Al-resistant genotype in an Al-inducible way (Magalhaes et al., 2007). Similarly, in barley (*Hordeum vulgare*) *HvMATE* expression in the root apices correlated with Al-activated citrate exudation and Al resistance in a set of barley cultivars (Furukawa et al., 2007). However, in contrast to these plant species, in common bean the *MATE* gene was highly expressed by Al within 4 hours of treatment in both an Al-resistant (Quimbaya) and an Al-sensitive (VAX 1) genotype. The expression of *MATE* was a prerequisite for citrate exudation, but the build-up of Al resistance within 24 h in Quimbaya exclusively depended on the capacity to sustain the synthesis of citrate for maintaining the cytosolic citrate pool that enabled continuous exudation (Eticha et al., 2010; Rangel et al., 2010). In addition, the genotype-independent initial Al-induced inhibition of root elongation and subsequent recovery in the Al-resistant genotype was closely correlated with the expression of the 1-aminocyclopropane-1-carboxylic acid oxidase (*ACCO*) gene (Eticha et al., 2010). It has been speculated that the Al-induced inhibition of root growth is due to enhanced gene expression and enzyme activity of *ACCO* resulting in increased ethylene production in *Lotus japonicus* and *Medicago truncatula* (Sun et al., 2007). Thus, it appears that the *MATE* gene behaves like an Al sensor in common bean independent on the Al resistance of the genotype, and the *ACCO* gene as an indicator of Al-induced inhibition of root

elongation.

The combined Al toxicity and drought stress on root growth, with special emphasis on Al/drought interaction in the root apex of common bean has been well studied. Using polyethylene glycol (PEG) to simulate osmotic stress (OS) or drought stress, we found that OS enhances Al resistance by inhibiting Al accumulation in the root apices of the Al-sensitive genotype VAX 1. This alleviation of Al toxicity was related to the alteration of cell wall (CW) porosity resulting from PEG 6000-induced dehydration of the root apoplast. A biochemical and molecular regulation of the OS-induced change of CW porosity has been proposed (Yang et al., 2010). The plant CW is a composite structure consisting of a cellulose-hemicellulose framework embedded within a pectic polysaccharides and proteins matrix (Carpita and Gibeaut, 1993). This viscoelastic semi-solid component is a decisive factor for its resistance to external stress. Water loss from the wall matrix can result in serious disruption to polymer organization. One obvious effect is that polymers usually well separated in the hydrated wall are brought into close proximity to each other, thus causing polymer adhesion or cross-linking under water stress (Moore et al., 2008). It has been reported that several proteins play key roles in the adjustment of cell-wall structure, such as expansin, xyloglucan endotransglycosylase (XET) and glucanase (Wu and Cosgrove, 2000; Cosgrove, 2005). Therefore, the identification genes particularly involved in CW modification appears to be necessary for a better understanding of PEG-induced reduction of root-tip Al accumulation.

Common bean is a molecularly under-researched crop; extensive microarray-based transcriptomic studies are not yet possible owing to the lack of available gene and expressed sequence tag (EST) information. Thus, less comprehensive approaches such as suppression subtractive hybridization (SSH) libraries need to be taken, which do not *per se* allow the quantification of the expression of differentially expressed genes (Molina et al., 2008). One powerful technique for gene expression analysis is the serial analysis of gene expression (SAGE) developed by Velculescu et al. (1995). However, the short tag sequence of only 13-15 bp generated from SAGE was not always sufficient to unequivocally identify the gene from which the tag was derived. A single tag sequence usually corresponded to several different ESTs and genomic sequences, which required further analysis (Matsumura et al., 2003). SuperSAGE is an improved version of SAGE which overcomes the limitations of SAGE by producing 26 bp long fragments from defined position in cDNAs, providing sufficient sequence information to unambiguously characterize the mRNAs (Matsumura et al., 2003; Molina et al., 2008). This technique has been

successfully applied in several gene expression studies (Matsumura et al., 2003; Hamada et al., 2008; Molina et al., 2008; Gilardoni et al., 2010).

The main objectives of this study were: (a) to describe the interaction of Al toxicity and OS (PEG) in the Al-sensitive common bean genotype VAX 1 at the molecular level; and (b) to identify OS-induced genes in the bean root tips using SuperSAGE with particular emphasis on genes related to CW modification, in order to better understand the OS-induced changes of CW structure and thus reduction of Al accumulation in the root tips at the transcriptional level.

Materials and Methods

Plant materials and growing conditions

Seeds of the common bean (*Phaseolus vulgaris* L.) genotype VAX 1 (Al-sensitive) were germinated on filter paper sandwiched between sponges. After three days, uniform seedlings were transferred to a continuously aerated simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ (Rangel et al., 2007). Plants were cultured in a growth chamber under controlled environmental conditions of a 16/8 h light/dark cycle, 27/25 °C day/night temperature, 70% relative air humidity, and a photon flux density of 230 μmol m⁻² s⁻¹ of photosynthetically active radiation at plant height. The pH of the solution was gradually lowered to 4.5 within two days. Then the plants were transferred into a solution (see above) without or with AlCl₃ (25 μM), PEG 6000 (150 g L⁻¹) and PEG 1000 (115 g L⁻¹) (Sigma-Aldrich Chemie GmbH, Steinheim, Germany), pH 4.5. Root tips (1-cm) were harvested for Al analysis or immediately frozen in liquid nitrogen in diethylpyrocarbonate (DEPC)-H₂O-treated Eppendorf vials for RNA isolation. The osmotic potentials (OPs) of both PEG 6000 (150 g L⁻¹) and PEG 1000 (115 g L⁻¹) solutions were -0.60 MPa, measured with a cryoscopic osmometer (Osmomat 030, Gonotec GmbH, Berlin, Germany).

Measurement of root-elongation rate

Two hours before the treatment was initiated, tap roots were marked 30 mm behind the root tip using a fine point permanent marker (Sharpie blue, Stanford) which did not affect root growth during the experimental period. Afterwards, the plants were transferred into a simplified nutrient solution (see above) without or with PEG in the absence or presence of Al. Root elongation was measured after the 24 h treatment period using a mm scale.

RNA isolation and construction of the SuperSAGE library

For construction of the SuperSAGE library, only PEG 6000 was used. After treating the plants with PEG 6000 for 24 h in a simplified nutrient solution (see above), the roots were rinsed with distilled water and five to six root tips (1 cm long) from each plant were harvested and shock-frozen in liquid nitrogen. Root tips of 10 plants per treatment were bulked and ground to powder in liquid nitrogen. Total RNA was isolated using the NucleoSpin RNA plant kit (MACHEREY-NAGEL GmbH and Co., KG, Düren, Germany)

following the manufacturer's protocol. From total RNA, poly(A)-RNA was purified with the Oligotex mRNA mini Kit (Qiagen) according to manufacturer's protocol.

SuperSAGE libraries were constructed by GenXPro GmbH (Frankfurt am Main, Germany) essentially as described by Matsumura et al. (2010). In order to avoid PCR bias during the amplification steps, GenXPro's "PCR-bias-proof technology" was employed to distinguish PCR copies from original tags. Sequencing was performed on an Illumina GA II machine (Illumina, Inc., San Diego, USA). For each library, 26 bp long tags were extracted from the sequences using the GXP-Tag sorter software provided by GenXPro GmbH (Frankfurt am Main, Germany). Sequencing artifacts were reduced according to Akmaev and Wang (2004).

Library comparisons were carried out using the DiscoverySpace 4.01 software (Canada's Michael Smith Genome Sciences Centre, available at <http://www.bcgsc.ca/discoveryspace>). Statistical analysis of differentially expressed tags was conducted using the probability (P)-value according to the description of Audic and Claverie (1997). The expression ratios of the 26 bp tags from control versus PEG 6000-treated roots were calculated as: Ratio (R) = $\log_2^{(\text{PEG6000}/\text{control})}$, after normalizing to one million. Tags that are present zero times are replaced by 0.05, to allow calculation of the ratio.

Sequence homology alignments

Tags sequences were BLASTed (Altschul et al., 1990) against different public databases (Phaseolus_TIGR_PHVGI.release_3/PHVGI.052909; TIGR_Phaseolus_cocc_TiGR_PCGI.Release_1/PCGR.052909; Glycine_MAX_TIGR_GMGI.release_14/GMGI.052909; Medicago_TIGR_MTGI.release_9/MTGI.071708; Lotus_TIGR_LJGI.release_5/LJGI.052909; Refseq_plant_June09/refseqPlantJune09.fna; All-plant-EST.fasta (plantGDB)).

Primer design for qRT-PCR

The ESTs from different organisms with high similarity to the sequences of candidate genes obtained from the SuperSAGE library were aligned, and the conserved regions were BLASTed against the *P. vulgaris* database. Finally the ESTs of *P. vulgaris* were aligned and the conserved region was used for primer design. Primers were designed using Primer3 software (Rozen and Skaletsky, 2000). The primers of the *β-tubulin*, *MATE* (multidrug and toxin extrusion) family protein and *ACCO* (1-aminocyclopropane-1-carboxylic acid

oxidase) genes were obtained from Eticha et al. (2010). The specifications of the primers of the genes studied in more detail are given in Tab. 1. For a complete list of all primers used see Supporting Information Table 1. The PCR efficiencies of the primer pairs were in the range of 90 – 110% as determined by dilution series of the cDNA template. Primer pairs with PCR efficiencies deviating from this range were discarded and new primers of the genes were designed to get more reliable quantification.

Table 1 List of main genes and specific primer pairs used for quantitative gene expression analysis

Candidate genes	Primer pairs (5'→3')*	Amplicon size (bp)	TC/GB Acc. No.
<i>LTP</i> (Protease inhibitor/seed storage/lipid transfer protein family protein)	(+) CCTCAGCAGCACAAAGATGAG (-) TGACAGCAATCTGAGGGTTG	147	CV542382

* (+) and (-) indicate forward and reverse primers, respectively.

First-strand cDNA synthesis and qRT-PCR

After isolating the RNA from 1-cm root tips of bean genotype VAX 1 (see above), first-strand cDNA was synthesized using RevertAid H-Minus first strand cDNA synthesis kit (Fermentas, www.fermentas.com) following the manufacturer's protocol. qRT-PCR was performed using the CFX96TM Real Time System plus C1000TM Thermal Cycler (www.bio-rad.com). The SYBR Green detection system was used with self-prepared SYBR Green master mix. The qRT-PCR reaction mix composed of 1× hot-start PCR buffer (DNA Cloning Service, Germany), 3.6 mM MgCl₂ (DNA Cloning Service, Germany), 200 μM each dNTP (dATP, dTTP dCTP dGTP) (Fermentas), 0.1× SYBR Green-I (Invitrogen), 0.75 U μL⁻¹ DCSHot DNA Polymerase (DNA Cloning Service, Germany), 252 nM each forward and reverse primer (Biolegio), 2 ng μL⁻¹ cDNA template and ultra-pure DNase/RNase-free distilled water (Invitrogen) in a final volume of 25 μL. The qRT-PCR cycling stages consist of initial denaturation at 95 °C (10 min), followed by 45 cycles of 95 °C (15 s), 60 °C (30 s), 72 °C (30 s), and a final melting curve stage of 95 °C (15 s), 60 °C (15 s) and 95 °C (15 s). Samples for qRT-PCR were run in three biological replicates and two technical replicates. Relative gene expression was calculated using the comparative ΔΔCT method according to Livak and Schmittgen (2001). For the normalization of gene expression, *β-tubulin* was used as an internal standard according to Eticha et al. (2010), and the control (non-treated) plants of bean genotype VAX 1 were used as reference sample.

Confirmation of SuperSAGE expression profiles via qRT-PCR

Parallel RNA extractions to the SuperSAGE library construction in 1-cm root tips from control (-PEG) and PEG 6000-treated plants were used. 46 differentially expressed genes according to SuperSAGE with putative role in the regulation of cell-wall properties and response to OS were selected and the primers were designed according to the method described above (Supporting Information Table S1). The expression of these genes in control and PEG 6000-treated 1-cm root tips of bean were confirmed by SYBR Green-based qRT-PCR.

Determination of Al

For the determination of Al, 1-cm root tips were digested in 500 μL ultra-pure HNO₃ (65%, v/v) by overnight shaking on a rotary shaker. The digestion was completed by heating the

samples in a water bath at 80 °C for 20 min. Then 1.5 mL ultra-pure deionised water was added after cooling the samples in an ice-water bath. Aluminium was measured with a Unicam 939 QZ graphite furnace atomic absorption spectrophotometer (GFAAS; Analytical Technologies Inc., Cambridge, UK) at a wavelength of 308.2 nm after appropriate dilution, and an injection volume of 20 µL.

Statistical analysis

A completely randomized design was used, with four to twelve replicates in each experiment. Statistical analysis was carried out using SAS 9.2. Means were compared using t or Tukey test depending on the number of treatments being compared. *, **, ***, and ns denote significant differences at $P < 0.05$, 0.01, 0.001, and not significant, respectively.

Results

Both PEG 6000 and PEG 1000 treatment induced the same extent of inhibition of root elongation (30%) of common bean at the same osmotic potential (OP) treatment level (Fig. 1A). Aluminium treatment strongly reduced root elongation (80%). Addition of PEG in the presence of Al significantly reduced the Al-induced inhibition of root elongation to 50% and 40% with PEG 1000 and 6000, respectively (Fig. 1A). The PEG-induced decrease in Al toxicity was related to a significant reduction of Al accumulation in the 1-cm root tips (PEG 6000 > PEG 1000, Fig. 1B).

The expressions of the citrate transporter *MATE* gene and the *ACCO* gene were clearly enhanced by increasing Al supply (Fig. 2A, B). The relative expression levels were significantly negatively correlated with root elongation as affected by Al supply (Fig. 2C, D) and positively correlated with the Al concentrations of the roots tips (Fig. 2E, F). This confirms the decisive role of root-tip Al accumulation in Al-induced inhibition of root elongation.

It thus appears that the expression of the *MATE* and *ACCO* genes are sensitive indicators of Al toxicity and Al accumulation, which could provide opportunities to further clarify the PEG-induced reduction of Al accumulation in the root tips. In contrast to Al stress, OS induced by PEG 1000 or PEG 6000 did not affect the regulation of both genes (Fig. 3). However, the Al treatment-induced up-regulation was significantly decreased by PEG treatment (PEG 6000 > PEG 1000) in agreement with the greater suppression of Al accumulation and Al stress by PEG 6000 (see Fig. 1).

The removal of PEG from the treatment solution rapidly allowed Al to accumulate in the root tips (Fig. 4A), and the expressions of *MATE* and *ACCO* genes were restored near to the level of the treatment with Al alone with the exception of *ACCO* in the PEG 1000-treated root tips (Fig. 4B, C).

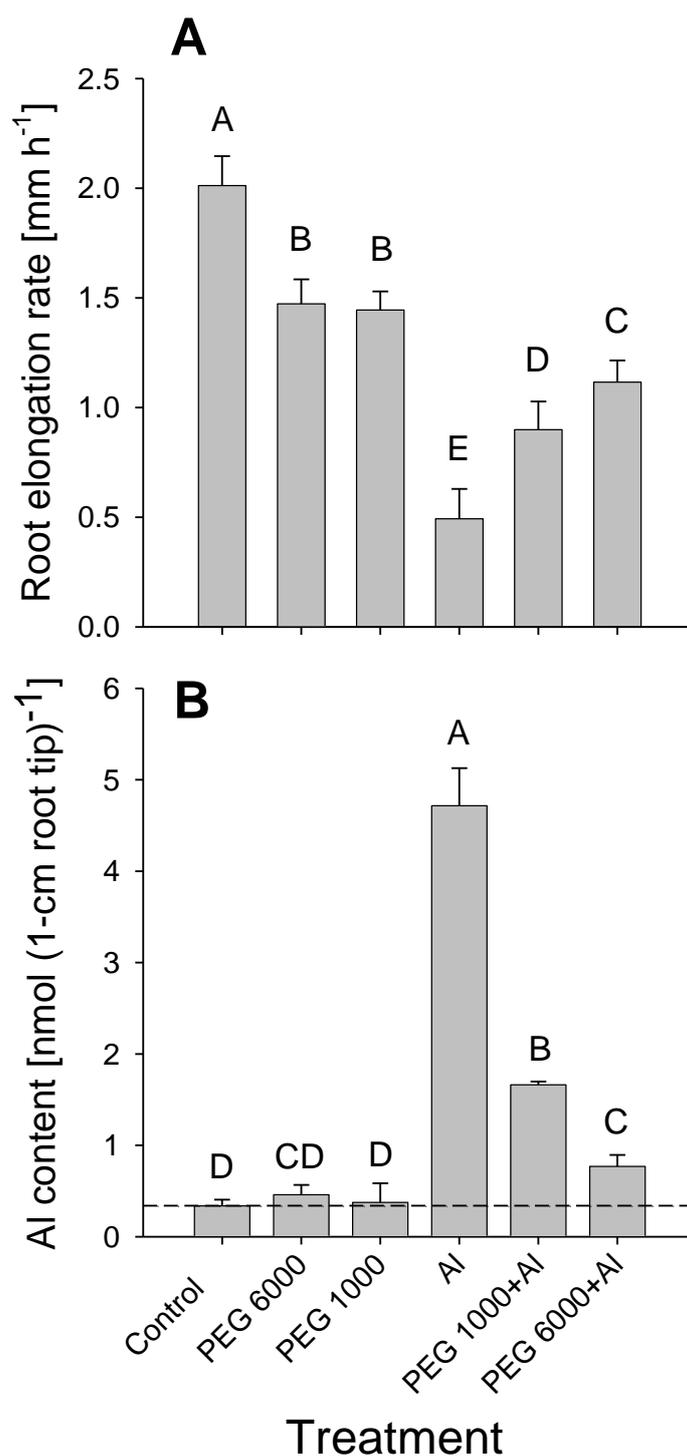

Figure 1 Root-elongation rate (A) and Al content (B) of 1-cm root tips of the common bean genotype VAX 1 under osmotic (0, -0.60 MPa OP) and Al (0, 25 μM Al) stresses. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, then treated without or with 25 μM Al in the absence or presence of PEG (150 g L⁻¹ PEG 6000, 115 g L⁻¹ PEG 1000) in the simplified nutrient solution for 24 h, pH 4.5. The background value (dashed line) in (B) represents the mean Al content of the root tips without Al treatment. Bars represent means \pm SD, $n = 12$ for (A) and $n = 4$ for (B). Means with different capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatments.

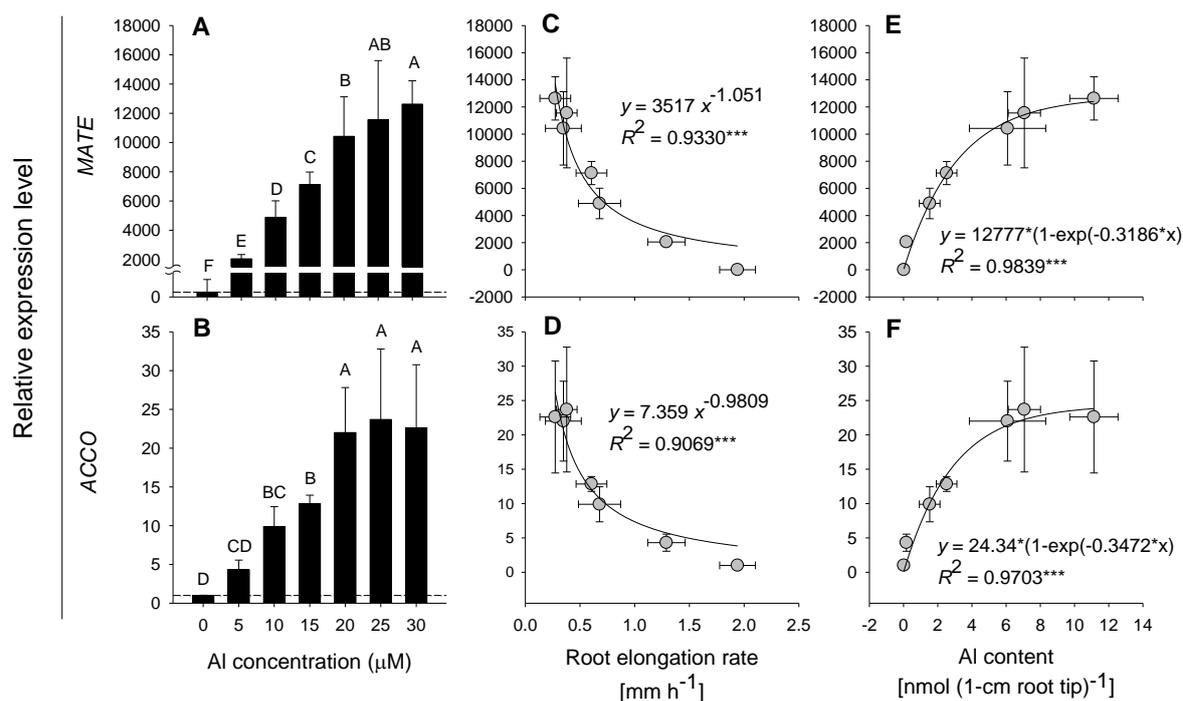

Figure 2 The effect of Al (0 - 30 μM) on the relative expression level of *MATE* and *ACCO* genes in 1-cm root tips of the common bean genotype VAX 1 and the correlation of the *MATE* and *ACCO* gene expression with root elongation rate and Al content. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, then treated with different concentrations of Al (0 - 30 μM) in the simplified nutrient solution for 24 h, pH 4.5. The background value (dashed line) in (A) and (B) represents the calibrated reference using untreated plants. qRT-PCR was performed using the β -*tubulin* gene as internal standard. Bars represent means \pm SD, $n = 4$ for root elongation rate and Al content, $n = 3$ for gene expression. Means with different capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments. *** denote significant differences at $P < 0.001$.

The results clearly showed that particularly PEG-6000 reduced the Al accumulation of root tips and that the Al accumulation of the same roots tips is rapidly restored upon withdrawing PEG. In order to better understand the molecular basis of the PEG effect, two libraries from control (-PEG 6000) and PEG 6000-treated root tips were constructed using SuperSAGE. After excluding the singletons from the total sequenced 9,015,356 tags of 26 bp length in both libraries (data not shown), we analysed in total 8,960,486 tags, 3,913,099 (44%) from the root tips of the control and 5,047,387 (56%) from PEG-treated plants (Table 2). These tags represented 75,867 unique transcripts (UniTags) overall, 67,185 (89%) from the PEG 6000-treated and 68,969 (91%) from the control roots; among these, 9,819 UniTags were up- and 8,019 UniTags were down-regulated at $P < 0.05$ (Fig. 5A, Table 2). UniTags present at < 100 , 100-1000 and > 1000 copies per million (copies \times million $^{-1}$)

were considered as low, mid and high abundant tags, respectively. The frequency distribution of the 68,969 UniTag in control library showed 0.2% low, 2.3% mid and 97.6% high-abundant tags, and the 67,185 UniTags in the PEG 6000 library showed 0.2% low, 2.4% mid and 97.5% high-abundant tags (Table 2). The annotation of the 75,867 UniTags matched 39,314 previously well characterized sequences from the public databases with a maximum of 5 mismatches (scores ≥ 42.1 ; about 52%). Of these, 28% matched to sequences from *P. vulgaris*, 6% to *Phaseolus coccineus*, 3% to *Glycine max*, 0.3% to *Medicago truncatula*, 0.2% to *Lotus japonicus*, and 15% to other species (Table 3).

Table 2 Features of SuperSAGE libraries from control and PEG 6000-treated root tips of common bean genotype VAX 1.

Library	Control	PEG 6000	Total
Sequenced tags	5,047,387 (56%)	3,913,099 (44%)	8,960,486 (100%)
Number of unique transcripts (UniTags)	68,969 (91%)	67,185 (89%)	75,867 (100%)
Abundance classes of UniTags*			
High-abundant: > 1,000 copies.million ⁻¹	104 (0.2%)	98 (0.2%)	-
Mid-abundant: 100 - 1,000 copies.million ⁻¹	1,578 (2.3%)	1,594 (2.4%)	-
Low-abundant: < 100 copies.million ⁻¹	67,287 (97.6%)	65,493 (97.5%)	-
Total	68,969	67,185	-

* Values normalized to 1 million tags

Table 3 BLAST search results of the SuperSAGE Unitags in different EST databases.

EST database	Control	PEG 6000	Total
<i>Phaseolus vulgaris</i>	19,147 (28%)	18,291 (27%)	21,121 (28%)

Not matched	33,871 (49%)	33,061 (49%)	36,553 (48%)
Total	68,969	67,185	75,867

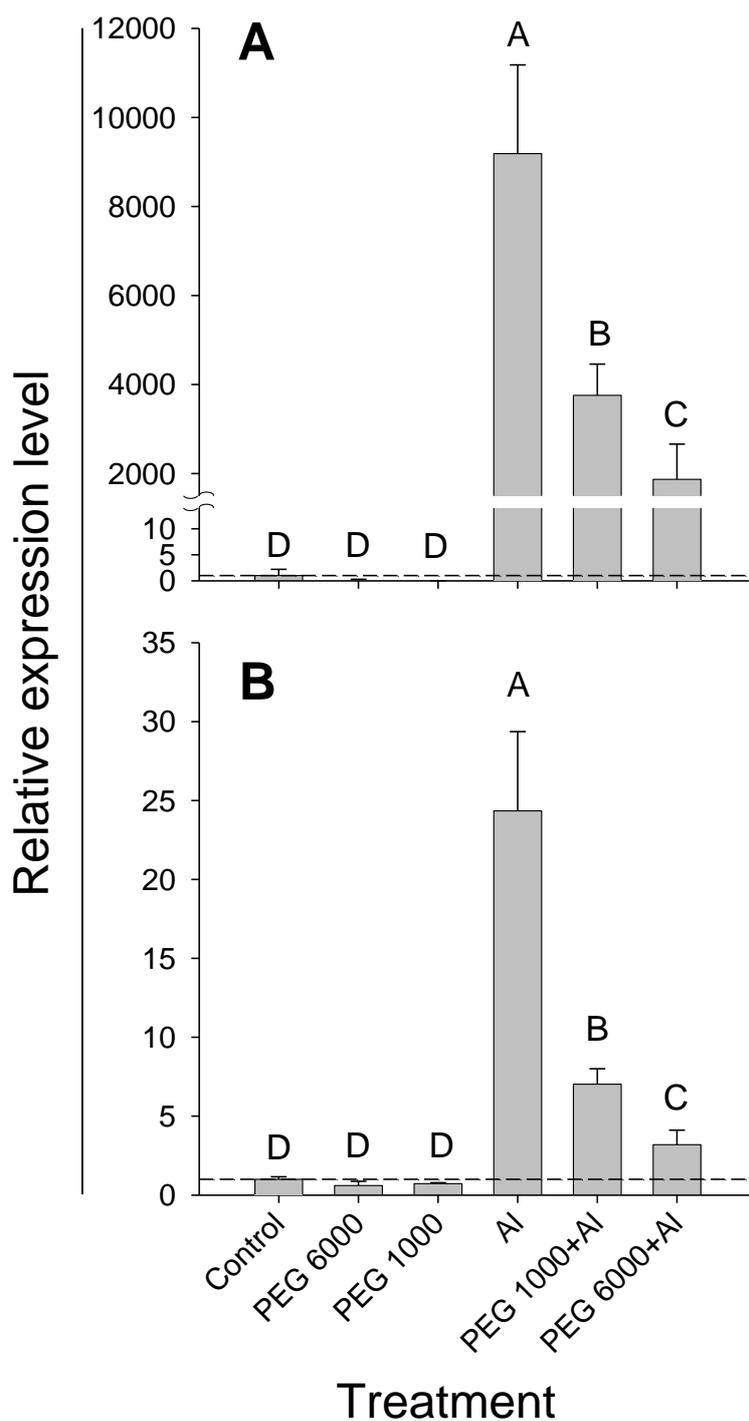

Figure 3 Relative expression level of *MATE* (A) and *ACCO* (B) genes in 1-cm root tips of common bean genotype VAX 1 under osmotic (0, -0.60 MPa OP) and Al (0, 25 μ M Al) stress. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μ M H_3BO_3 for 48 h for acclimation and pH adaptation, then treated without or with 25 μ M Al in the absence or presence of PEG (150 g L^{-1} PEG 6000, 115 g L^{-1} PEG 1000) in the simplified nutrient solution for 24 h, pH 4.5. The background value (dashed line) represents the calibrated reference using untreated plants. qRT-PCR was performed using the *β -tubulin* gene as internal standard. Bars represent means \pm SD, n = 3. Means with different capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatments.

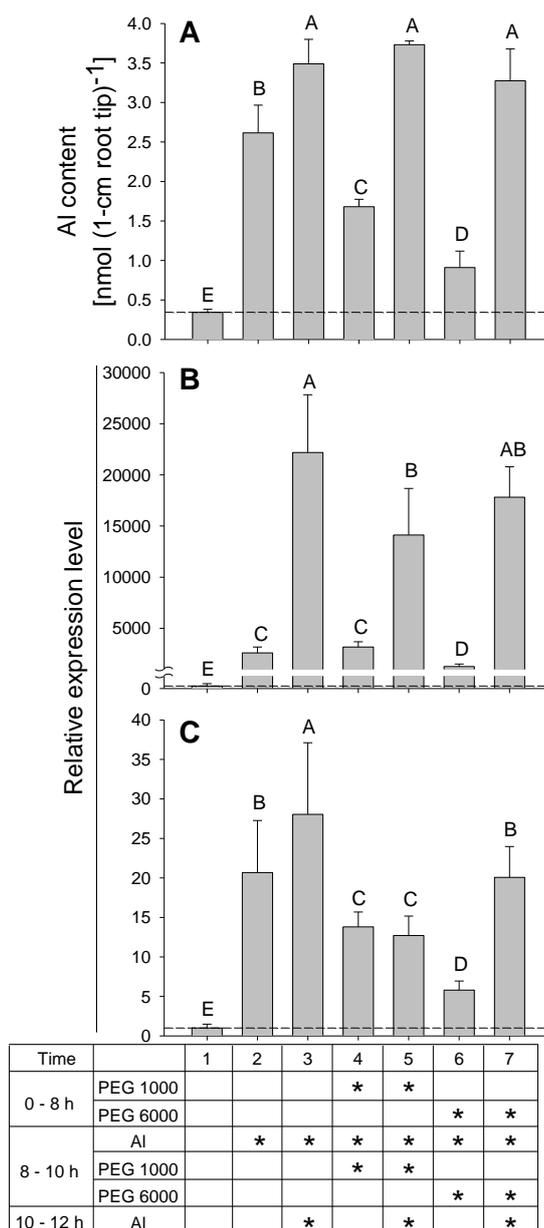

Figure 4 Al content (A) and relative expression level of *MATE* (B) and *ACCO* (C) genes in 1-cm root tips of common bean genotype VAX 1 under osmotic (-0.60 MPa OP) and Al stress. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ for 48 h for acclimation and pH adaptation, then the plants were subjected to a series of Al (0, 25 μM), PEG 6000 (0, 150 g L⁻¹) and PEG 1000 (0, 115 g L⁻¹) treatment solutions. A detailed description of the different treatments are shown under figure with a table. Different numbers (1 - 7) represent different Al and PEG treatment combinations, and * indicate the presence of treatment. Briefly, the plants were pre-treated with either PEG 1000 or PEG 6000 for 8 h. They were then transferred for 2 h (8-10 h) to a solution containing Al and/or PEG or not. This treatment was then followed by a 2 h (10-12 h) recovery period from PEG stress in presence or absence of Al. The background value (dashed line) represents the calibrated reference using untreated plants. qRT-PCR was performed using the *β-tubulin* gene as internal standard. Bars represent means ± SD, n = 4 for (A) and n = 3 for (B, C). Means with different capital letters are significantly different at *P* < 0.05 (Tukey test) for the comparison of treatments.

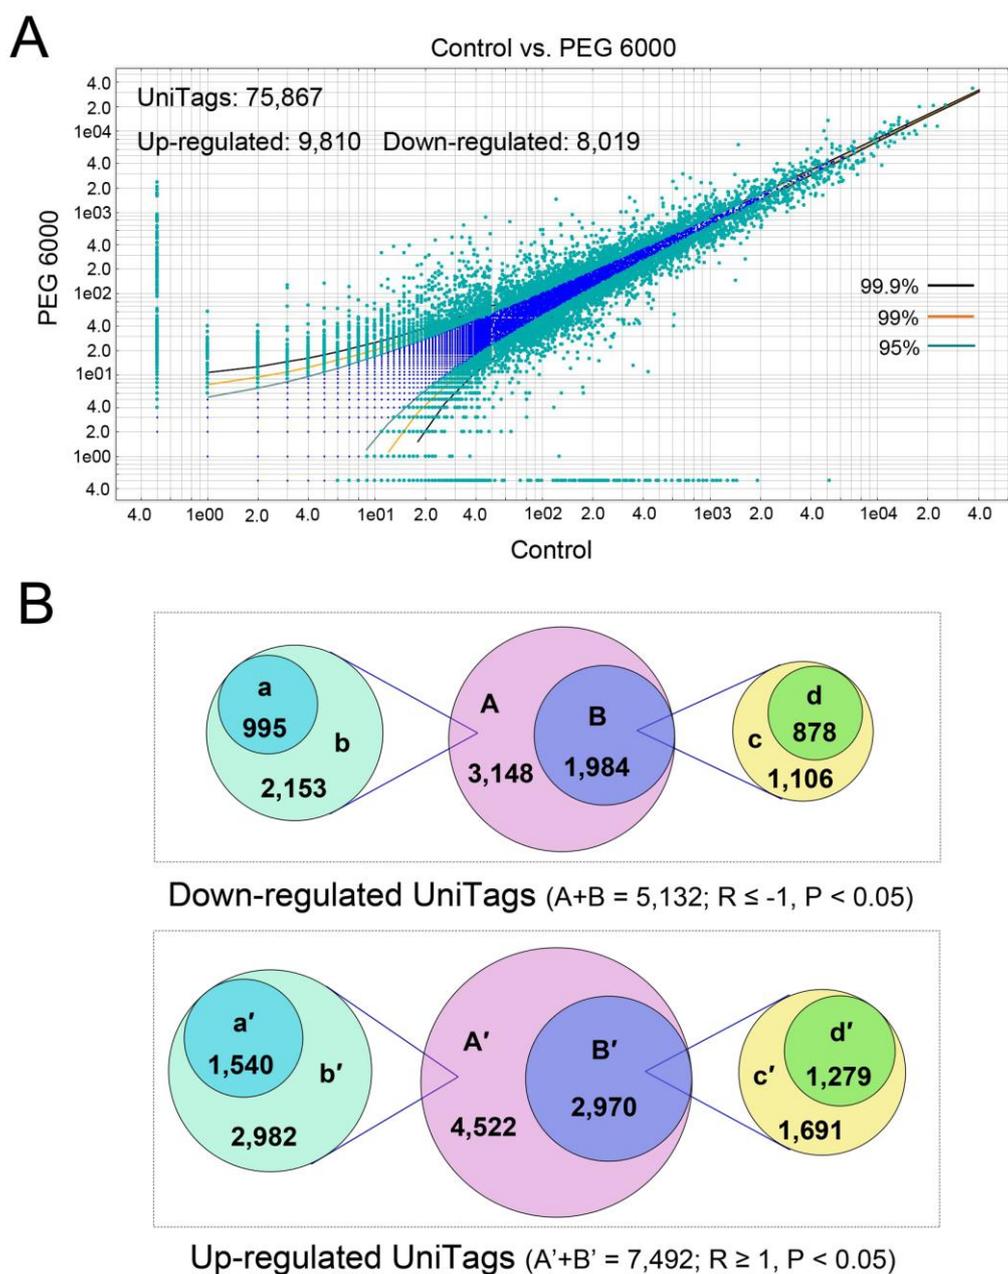

Figure 5 (A) Scatter plot showing the UniTags expressed in control and PEG 6000-treatment libraries. (B) Venn diagram showing down and up-regulated UniTags using rigorous threshold parameters ($|R| > 1$; $P < 0.05$) in root tips of common bean genotype VAX 1. In (A), lines represented as 99.9%, 99% and 95% demarcate UniTags that are significantly up- or down-regulated at P value lower than 0.001, 0.01 and 0.05, respectively. In (B), A/A': UniTags exclusively expressed in control/PEG 6000 libraries; B, B': in both libraries; a, d, a', d': no hit and b, c, b', c': hit to previously known public databases.

For further analysis of the PEG-induced differentially expressed genes, the significant differences in abundance of UniTags in control and PEG subjected roots were rigorously limited to a threshold $|R| \geq 1$ (≥ 2 -fold change) and $P < 0.05$. Based on this, a total of 12,624 UniTags (7,492, up-regulated; 5,132, down-regulated) were differentially expressed (Fig. 5B), and of these, 3,259 down-regulated UniTags (2,153 exclusively expressed in control and 1,106 expressed in both control and PEG treatment libraries) and 4,673 up-regulated UniTags (2,982 exclusively expressed in control and 1,691 in expressed in both control and PEG treatment libraries) hit to previously known sequences from *P. vulgaris*, *P. coccineus*, *G. max*, *M. truncatula*, *L. japonicus* and other organisms (Fig.5B). By assembling the same expressed sequence transcripts (ESTs) from the differentially expressed UniTags annotation in control and PEG 6000-treated roots, and the exclusion of the UniTags with more than six 3'-poly(A) in the 26 bp tags, finally a total of 611 up- and 728 down-regulated transcripts were obtained for the gene functional categorization (Fig. 6, Supporting Information Table S2). The gene functional categories of the differentially expressed transcripts were BLASTed against the non-redundant GeneBank and UniProt protein databases (<http://www.uniprot.org/>) by the gene ontology (GO) annotation (Supporting Information Table S2).

The unique transcripts were categorized and identified according to the functional category defined by KEGG PATHWAY and UniProt protein database (Fig. 6). About 47.5% of the up and 42.0% of the down-regulated transcripts had unknown functions or were unclassified. The metabolism categories (12.4%, up; 11.8%, down) were sub-classified into carbohydrate, energy, amino acid, lipid, nucleotide, secondary and other metabolic pathways. Functional categories equally up and down-regulated were transcription regulation (5.89%, up; 5.22%, down) and cytoskeleton (0.33%, up; 0.41%, down). Predominantly down-regulated transcripts by PEG were found in the categories of signal transduction, transport, stress/defence, cell-wall synthesis and organization, protein posttranslational modification, whereas transcripts in the categories of protein translation, processing and degradation, RNA processing and modification, replication and repair were more often up-regulated (Fig. 6). The differentially regulated UniTags with different functional categories were listed (Supporting Information Table S2).

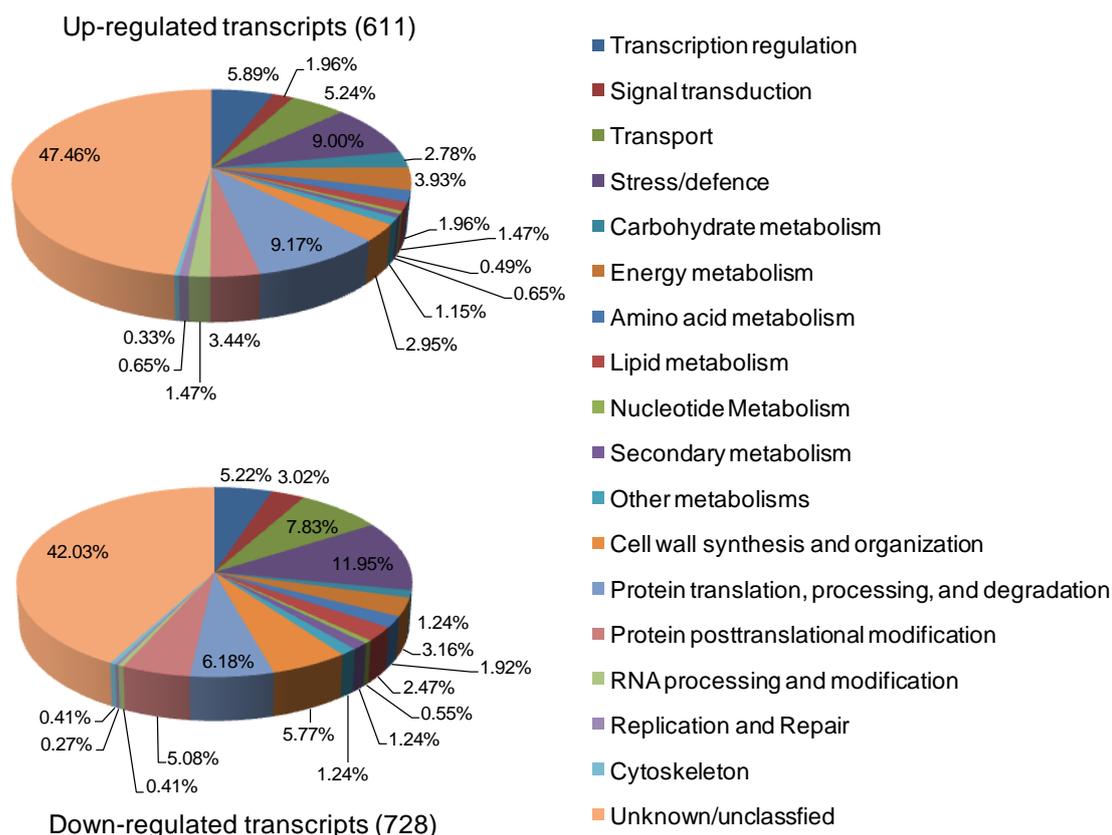

Figure 6 Functional categories of differentially expressed transcripts in control and PEG 6000-treated root tips of common bean genotype VAX 1.

To validate the results generated from SuperSAGE, 46 differentially expressed genes (Supporting Information Table S1) according to SuperSAGE with putative role in the regulation of cell-wall properties and response to OS were selected and their expression tested by quantitative real-time PCR (qRT-PCR). A highly significant correlation ($R^2 = 0.71$, $P < 0.0001$) between SuperSAGE and qRT-PCR was found (Fig. 7).

Among the 46 genes, six genes each with suspected functions in PEG-induced cell-wall modification (*XTHa*, *XTHb*, *BEG*, *HRGP*, *PRP* and *LTP*) and osmotic-stress response (*bZIP*, *MYB*, *AQP*, *P5CS*, *SUS* and *CYP701A*) were selected for a more detailed gene expression study using qRT-PCR (Fig. 8). The results showed that among the CW-associated genes only *LTP* and *HRGP* were significantly up-regulated by PEG treatment, whereas *XTHa*, *XTHb*, *BEG*, and *PRP* were down-regulated. All OS-associated genes were significantly up-regulated with the exception of *CYP701A*. Removal of the PEG stress for 2 hours which allowed root elongation rate to recover (data not shown) and partly restored the AI accumulation capacity (see Fig. 4), did reverse the gene expression to the control level for *XTHa*, *BEG*, and *HRGP* among the cell wall-associated genes and

bZIP, *MYB*, and *P5CS* among the OS-associated genes. The *LTP*, *SUS*, and *AQP* genes remained up-regulated and *PRP*, *XTHb*, *CYP701A* down-regulated compared to the controls. These results were highly reproducible because similar results were found in another experiment where root tips were treated only for 10 h compared to 24 hours as in the current experiment (data not shown).

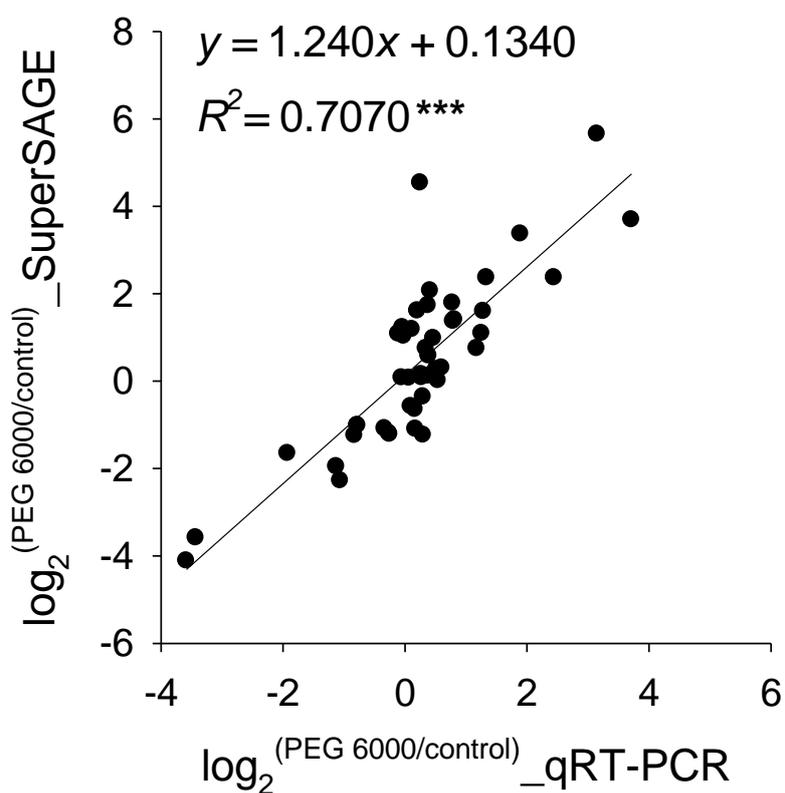

Figure 7 Validation of the PEG-induced expression of 46 genes selected from SuperSAGE in root tips of common bean genotype VAX 1 by qRT-PCR.

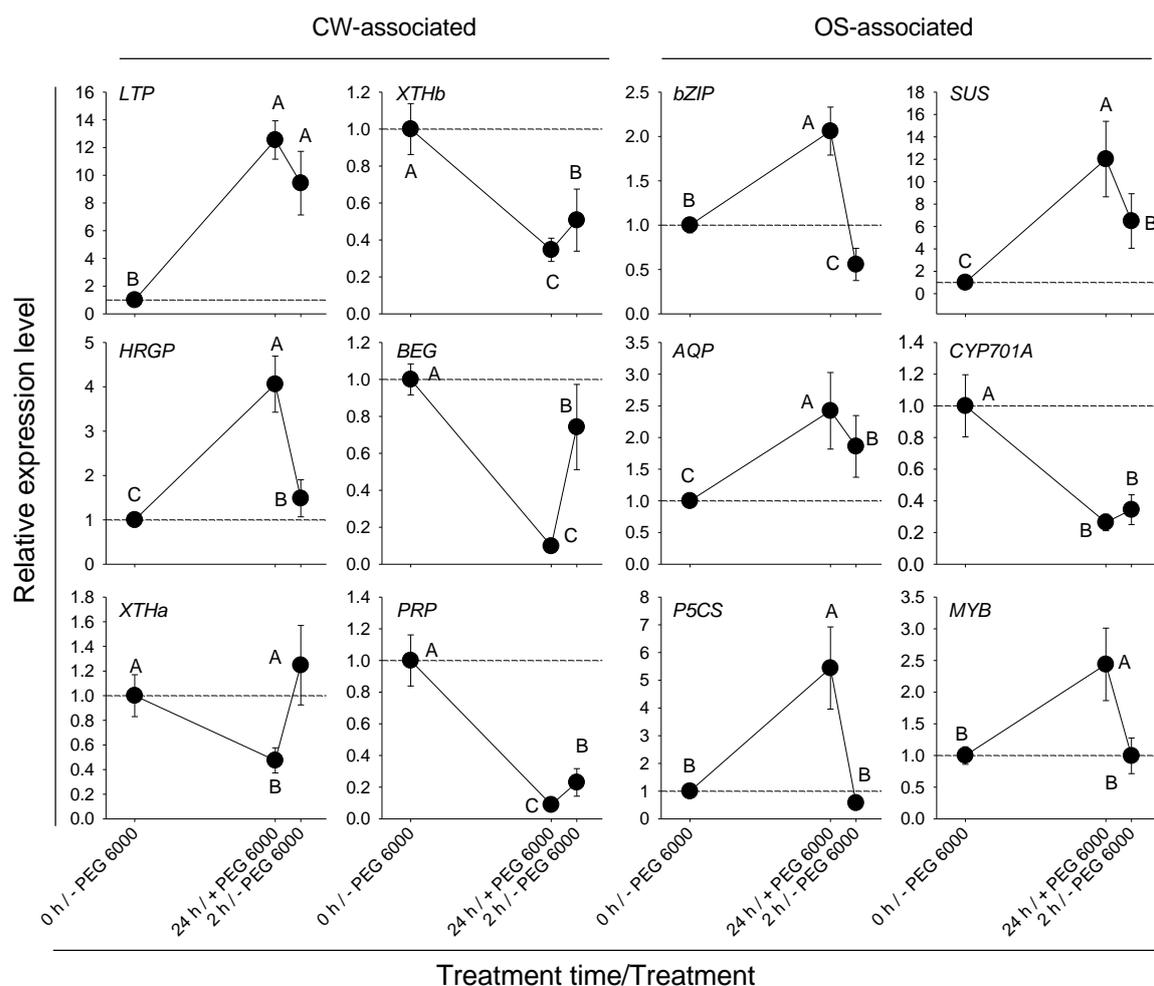

Figure 8 Relative expression level of CW- and OS-associated genes in 1-cm root tips of common bean genotype VAX 1 under OS (-0.60 MPa OP). Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, then the plants were transferred into a simplified nutrient solution containing PEG 6000 (150 g L^{-1}) for 24 h; then the plants were allowed to recover in a simplified nutrient solution for 2 h. The background value (dashed line) presents the calibrated reference using untreated plants. qRT-PCR was performed using the β -*tubulin* gene as internal standard. Bars represent means \pm SD, $n = 3$. Means with different capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatment periods.

Discussion

In the CW of the root apex Al is primarily bound to the negatively charged carboxylic groups (COO^-) provided by de-methylated pectin (Blamey et al., 1990; Horst, 1995; Horst et al., 2010). The exclusion of Al from the root tip apoplast is a prerequisite for the reduction of Al-induced inhibition of root elongation and thus Al resistance in common bean which is conferred by citrate exudation (Rangel et al., 2009; Horst et al., 2010). The role of Al exclusion from the root tip for Al resistance is corroborated by the current study demonstrating that the PEG (OS)-induced improvement of root growth under Al stress was related to a reduction of Al accumulation in the root tip (Fig. 1). The PEG (OS)-induced reduction of Al accumulation was due neither to enhanced citrate exudation, precipitation or complexation of Al^{3+} in the PEG treatment solution nor to reduction of CW negativity, but was attributed to the reduction of cell-wall porosity which limits the Al flux into the apoplast (Yang et al., 2010). This conclusion is based on the specificity of the exclusion for Al compared to La, Sr, and Rb and is consistent with their hydrated ionic radii ($\text{Al}^{3+} > \text{La}^{3+} > \text{Sr}^{2+} > \text{Rb}^+$) (Yang et al., 2010). In this study, a higher reduction of Al accumulation in PEG 6000 than in PEG 1000-treated plants was observed (Fig. 1). This differential change in Al accumulation is related to the molecular size and the estimated hydrodynamic radius ($\text{PEG 6000} > \text{PEG1000}$) of the applied PEGs. The higher the hydrodynamic radius of the osmotic solute, the better was the exclusion from the apoplast and thus the higher level of dehydration of the apoplast (Kuga, 1981; Yang et al., 2010). The removal of PEG from the pre-treatment solution quickly allowed accumulation of Al in the root tip (Fig. 4A) indicating that the CW can rapidly recover from the shrinkage and structural alteration caused by OS independent of the osmotic solute used.

In agreement with the highly sensitivity reaction of the *MATE* and *ACCO* gene expression in response to Al in common bean reported by Eticha et al. (2010), a significant correlation among *MATE* and *ACCO* gene expression, root elongation and the Al concentration in the root tips of common bean was found (Fig. 2). PEG treatment alone had no effect on the expression of both genes (Fig. 3) providing opportunities to further clarify the PEG-induced reduction of Al accumulation in the root tips and Al-induced inhibition of root elongation using the expression of the *MATE* and *ACCO* genes as sensitive indicators of Al toxicity. As expected, the OS-induced exclusion of Al from the root apex and the improvement of root growth were accompanied by a decrease in gene expression of *MATE* and *ACCO* (Fig. 2) confirming that OS reduces Al injury.

In this study the results generated from SuperSAGE could be well confirmed by qRT-PCR in OS-treated bean root tips (Fig. 7), indicating the reliability of SuperSAGE. However, about 49% of the UniTags generated from SuperSAGE did not match with previously known genome and EST sequences found in public databases (Table 3). This may have hampered the identification of genes responding to OS in the root tips. Among the differentially expressed genes approximately 55% of the unitags matched to *P. vulgaris* EST databases (Table 3). The fact that nearly half of the tags generated by SuperSAGE did not match with previously known sequences could be attributed to the nature of the 26 bp tags. The 26 bp tag fragments were isolated from the NlaIII recognition site (5'-CATG-3') closest to the poly-A tail of the cDNA, which in most cases lie in the 3' untranslated region (3' UTR). Therefore, it appears that the 3' UTR of common bean transcripts are very specific that they did not match with previously known sequences.

Although SuperSAGE is a powerful tool for quantitative gene expression analysis as well as for the discovery of novel genes, the method may miss out some transcripts. Particularly, transcripts which do not have the NlaIII restriction site (5'-CATG-3'), and those which have the restriction site extremely closer to the poly-A tail cannot be recognized. Based on *in silico* sequence data analysis of Arabidopsis RefSeq database, Matsumura et al. (2010) reported that, within 35,286 genes, 2,000 genes (5.7%) did not have NlaIII restriction site. Similarly in common bean, some genes which lack the recognition site for the anchoring enzyme, NlaIII, might have been missed out.

Drought-induced genes were classified into two groups according to microarray analysis in *Arabidopsis* (Shinozaki et al., 2003). The first group code for proteins which probably function in stress tolerance, such as late embryogenesis abundant proteins, osmotin, key enzymes for osmolyte biosynthesis such as proline, water channels, sugar and proline transporters, and lipid-transfer proteins. It has been reported that dehydration induced the expression of osmoregulation-related genes such as Δ^1 -pyrroline-5-carboxylate synthase (*P5CS*), sucrose synthase (*SUS*) in the resurrection plant *Craterostigma plantagineum* (Kleines et al., 1999; Rodriguez et al., 2010), maize (*Zea mays*) (Zheng et al., 2004; Spollen et al., 2008) and *Arabidopsis* (Oono et al., 2003). Overexpression of the *P5CS* gene in various plants resulted in elevated proline production and improved OS tolerance (Bartels and Sunkar, 2005). Also, it was found that some water transport-related *AQPs* (aquaporin family protein) genes were up-regulated by drought in *Arabidopsis*, upland rice (*Oryza sativa*) and grapevine (*Vitis vinifera*) (Alexandersson et al., 2005, 2010; Lian et al., 2006; Vandeleur et al., 2009), which may trigger greater membrane water-permeability

facilitating water flux (Bartels and Sunkar, 2005).

The second group comprises genes coding for regulatory proteins involved in signal transduction and transcription factors such as *bZIP*, *MYB*, *MYC* and *DREB* (Shinozaki and Yamaguchi-Shinozaki, 2007). The *bZIP* and *MYB* genes are transcription factors involved in an ABA-dependent pathway mediating gene expression in plants during OS (Shinozaki and Yamaguchi-Shinozaki, 2007). Rodriguez-Uribe and O'Connell (2006) found that a root-specific *bZIP* transcription factor is responsive to water deficit in tepary bean (*Phaseolus acutifolius*) and common bean, which may allow the plant to maintain root elongation. More recently the *OsZIP23* gene in rice and the *MYB96* gene in *Arabidopsis* were found to confer drought resistance (Xiang et al., 2008; Seo et al., 2009). In addition, the cytochrome P450s superfamily (CYP) may serve as mono-oxygenases involved in the biosynthesis of metabolites conferring abiotic stress tolerance (Schuler and Werck-Reichhart, 2003).

Based on this information, the OS-associated genes *SUS*, *P5CS*, *AQP*, *CYP701A*, *bZIP*, and *MYB* were selected to underpin the PEG-induced dehydration and rehydration in the root tips in the present study. All of these genes were significantly up-regulated by OS stress with the exception of *CYP701A*, while the removal of the PEG stress for only two hours rapidly reversed the gene expression to the control level for *P5CS*, *bZIP* and *MYB* (Fig. 8), suggesting a differentially response of gene expression to dehydration and rehydration in common bean. The quick reversal of *bZIP* and *MYB* genes expression after removal of the PEG stress may support the recovery of root elongation within two hours (data not shown) by mediating the expression of ABA-regulated genes, since it was reported that in maize the accumulation of ABA in the root tips is required for the maintenance of primary root elongation at low water potentials (Sharp et al., 2004). *P5CS* catalyzes the first committed and rate-limiting step for proline biosynthesis in plants (Kavi Kishor et al., 2005). Besides osmotic adjustment, proline also functions as a major constituent of CW structural proteins in plants (Nanjo et al., 1999). In *P5CS* antisense transgenic *Arabidopsis thaliana* plants proline (pro) and hydroxyproline (hyp) contents in hydrolysates of a purified CW fraction were specifically and significantly reduced indicating that proline deficiency affected the biosynthesis of CW matrix proteins, such as proline-rich proteins (PRPs) and hydroxyproline-rich glycoproteins (HRGPs) (Nanjo et al., 1999) which could provide mechanical support for cells under stressed conditions (Cosgrove, 1997). Therefore, the rapid reversal of *P5CS* gene expression after the removal of PEG stress may allow recovery of CW porosity by modifying the CW structural

properties. For further discussion of the OS-induced expression of *PRP* and *HRGP* genes see below in the discussion.

Among the OS-regulated genes, CW synthesis and organization-related genes were mostly down-regulated (Fig. 6) providing an opportunity to identify genes involved in the OS-induced alteration of CW porosity. Water loss in plant tissues reduces turgor pressure and so directly affects the extensibility of the plant CW. In maize, Sharp et al. (2004) reported that the extent of osmotic adjustment in root tip is insufficient to maintain turgor under severe water deficit. The maintenance of root elongation requires the enhancement of longitudinal CW extensibility under water stress (Sharp et al., 2004; Yamaguchi and Sharp, 2010). Some genes may play a role in CW extension during dehydration. For example, it was reported that *LTP* (lipid transfer proteins) are associated with hydrophobic wall compounds, causing non-hydrolytic disruption of the cell wall and subsequently facilitating wall extension in tobacco (Nieuwland et al., 2005). Our study showed that the expression of an *LTP* gene in the root tips of bean was significantly enhanced by OS (Fig. 8) suggesting that this gene may contribute to the maintenance of the root elongation of common bean under OS (Fig. 1).

Structural proteins are one of the main components of the growing plant CW. The CW structural proteins were classified according to their predominant amino acid composition, e.g. *HRGP*, glycine-rich protein, and *PRP* (Cosgrove, 1997). In our studies, we observed differential expression of genes encoding *HPRG* and *PRP* proteins in the root tips of common bean by OS (Fig. 8, Supporting Information Table S2). These proteins can rapidly be insolubilized in the CW during stress condition, such as upon wounding (Showalter, 1993; Cosgrove, 1997). In contrast, two proline-rich glycoproteins of 33 and 36 KDa (p33 and p36), similar to soybean *PRP2*, were highly accumulated in the soluble fraction of the cell walls in common bean in response to water deficit (Covarrubias et al., 1995; Battaglia et al., 2007). However, this does not exclude that higher amounts of proline-rich glycoproteins are tightly bound with the CW polymers in immobilized form, since only very low amounts of p33/p36 were detected in the soluble fraction of cell walls of well watered bean hypocotyls, while immunolocalization indicated that these proteins were abundantly localized in the cell corners of the cortex, epidermis, pith, vascular cells and phloem. However, we found that the expression of one *PRP* gene was significantly suppressed by OS and recovery of roots from OS could not rapidly restore the expression of this gene, which was in contrast with the *HRGP* gene (Fig. 8). The expression of a *HRGP* gene was significantly enhanced by OS, and withdrawing of OS rapidly restored the

expression of this gene (Fig. 8). The HRGP proteins are particularly abundant in dicots compared to other structural proteins (Showalter, 1993); thus the role of the *HRGP* gene appears to be important in the OS-induced modification of the CW in common bean. Once the HRGP is secreted into the wall, it will be rapidly insolubilized. The insolubilization of HRGP may be mediated by the water deficit-induced enhancement of hydrogen peroxide and catalyzed by a CW peroxidase. This response is thought to be an ultra-rapid stress-response reaction that serves to further strengthen the cell wall (Showalter, 1993; Zhu et al., 2007).

It has been reported that the pectin matrix is the decisive factor of CW porosity (Baron-Epel et al., 1988). Although the pectin content in the root tips of bean was reduced approximately by 25% due to PEG 6000-induced OS (Yang et al., 2010), this level of decrease of pectin content may not drastically alter CW porosity. It thus appears that the reduction of CW porosity may be largely due to the physical shrinkage of the CW and further enhanced by the deposition of other wall components, such as structural proteins as schematically depicted in Fig. 9A. The increased deposition of HRGP proteins in the wall may increase the cross-link between HRGP proteins and other wall components, such as pectin (Showalter, 1993), and further reinforce a cell-wall barrier, thus impeding Al uptake (Fig. 9B).

The shrinkage of the CW resulting from PEG 6000-induced dehydration of the apoplast causes adhesion and cross-linking of wall polymers through hydrogen bonding. This bonding will be enhanced by removal of water from the apoplast and is likely to cause an irreversible bonding between polymers resulting in altered biophysical CW properties (Fig. 9A; Moore et al., 2008; Yang et al., 2010), unless some CW loosening or modifying genes/enzymes were re-induced/activated. In *Arabidopsis*, water deficit consistently down-regulated the expression of genes involved in CW synthesis and modification (Bray, 2004). Similarly, also in common bean the number of down-regulated genes related to CW synthesis and organization under OS was two-fold higher than that of up-regulated genes (Fig. 6). Several CW proteins/enzymes are believed to play key roles in modifying the wall structure and controlling wall extension. These include expansin, xyloglucan endotransglucosylase/hydrolase (XTH), and glucanases (Wu and Cosgrove, 2000; Bray, 2004; Sharp et al., 2004; Moore et al., 2008).

The XTH proteins are a large family of CW proteins which have 33 members known in the *Arabidopsis* genome, and they are involved in controlling CW extensibility through the

cleavage and reformation of bonds between xyloglucan chains (Rose et al., 2002; Bray, 2004). Under soil moisture deficit, the genes encoding XTH were among the commonly down-regulated genes when 23 genes annotated in the *XTH* family were analyzed (Bray, 2004). In Chickpea (*Cicer arietinum*) Romo et al. (2005) found that the expression of the *CaXTH1* gene encoding the XTH protein was repressed by PEG treatment which inhibited epicotyl growth. The removal of PEG resulted in restoration of the normal expression level of this gene suggesting the involvement of XTH encoded by *CaXTH1* in cell-expansion. Spatial analysis of CW proteomics in maize primary roots indicated that the abundance of XTH proteins was significantly reduced by water deficit in the first three millimeters of the root apex (Zhu et al., 2007). In the present study, qRT-PCR results showed that the expressions of *XTHa* and *XTHb* genes in the root tips of common bean were significantly reduced by PEG-induced dehydration of the apoplast (Fig. 8). Withdrawal of PEG from the pre-treatment solution rapidly allowed the recovery of the expression level of the *XTHa* gene (Fig. 8), supporting the view that the *XTHa* gene may be involved in the CW modification during the recovery period of the apoplast from dehydration (Fig. 9B).

In addition, Glucan endo-1,3-beta-glucosidase (or beta-1,3-glucanase) (BEG) may also play an important role in the OS-induced wall modification and thus influencing AI accumulation that was observed in the present study (Fig. 9B). BEGs are abundant proteins found in all higher plants. They are known to be involved in pathogen defense as well as a wide range of normal developmental processes and can hydrolytically cleave the 1,3- β -linked glucans, a major component of the fungal cell wall (Minic and Jouanin, 2006). BEG belongs to the family of 17 plant glycoside hydrolases, and molecular studies suggested that this enzyme shares a common ancestry with beta-1,3-1,4-glucanase (Minic and Jouanin, 2006; Borad and Sriram, 2008). Although the function of many cell-wall enzymes has yet to be determined, a role of BEG in the OS-induced CW modification of common bean root tips in the present study is likely, since PEG-induced OS significantly reduced the *BEG* gene, but removal of PEG rapidly recovered its expression (Fig. 8). Wu et al. (2001) reported that the induction of BEG in the micropylar tissues of imbibed tomato (*Lycopersicon esculentum* Mill.) seeds can be inhibited by ABA. Therefore, the expression of the *BEG* gene may be repressed by the OS-induced accumulation of ABA in the root apex of plants. This is corroborated by the observation that water deficit increased the accumulation of ABA in the root apex of maize (Sharp et al., 2004; Yamaguchi and Sharp, 2010), which consequently reduced the abundance of BEG proteins in the root tips (Zhu et al., 2007).

In the present study, PEG treatment by itself inhibited root growth by 30% compared to the control, possibly by reducing CW expansion. While sole Al treatment inhibited root growth by 80%, combined Al and PEG treatment only resulted in 40% inhibition (See Fig. 1A). Therefore, the PEG-induced recovery from Al injury resulted from the reduced Al accumulation in the root tips of common bean as a consequence of PEG-induced reduction of CW porosity (Yang et al., 2010). The enhanced expression of the *HRGP* and reduced expression of the *XTH* and *BEG* genes may contribute to the reduction of CW porosity, but the main cause of the reduction of CW porosity by PEG is the osmotic stress-induced physical collapse of CW structure (presented in Fig. 9A). The main role of *HRGP*, *XTH* and *BEG* is the involvement in the recovery of CW porosity (Fig. 9B).

In conclusion, our results suggest that several CW modifying- and assembling-related genes such as *XTHs*, *BEG* and *HRGP* may play important roles in the PEG (OS)-induced changes of CW porosity leading to reduced Al accumulation in the root tips. There is a need for further research to determine the role of functional genes related to CW modification under conditions of water deficit.

Abstract

Previous work showed that PEG induced osmotic stress reduced cell-wall (CW) porosity limiting aluminium (Al) uptake by root tips of common bean (*Phaseolus vulgaris* L.). A subsequent transcriptomic study provided genes involved in CW adjustment to osmotic stress. In this study a proteomic approach was used to analyze osmotic stress-induced proteins to further improve our understanding of how osmotic stress affects Al accumulation. Analysis of total soluble proteins in root tips indicated that in total 22 proteins were differentially regulated by osmotic stress; these proteins were functionally categorized. 77% of the total expressed proteins were involved in metabolic pathways particularly of the carbohydrate and amino acid metabolism. An apoplastic proteomic analysis suggested that five proteins were reduced and seven proteins were increased by osmotic stress. Investigation of the total soluble phosphoproteome highlighted dehydrin of which the phosphorylation state was increased but not its abundance under osmotic stress. This is supposed to play a major protective role in the osmotic stress-induced physical breakdown of the CW structure and thus the maintenance of the reversibility of CW extensibility during recovery from osmotic stress. The proteomic analysis provided novel insights into the complex mechanisms of osmotic stress-induced reduction of Al accumulation in the root tips of common bean and highlights a key role of CW structure modification.

Key words: apoplast, cell wall, common bean, phosphoproteomics, proteomics, dehydrin, root tips

Introduction

Common bean (*Phaseolus vulgaris* L.) is the major food legume for human nutrition worldwide, and a major source of calories and protein particularly for people in undeveloped countries in the tropics (Graham, 1978; Rao, 2001). Under field conditions, common bean often experiences different abiotic stresses including drought, toxicities of aluminium (Al) and manganese, low soil fertility, and high temperatures (Thung and Rao, 1999; Singh, 2001; Ishitani et al., 2004). About 60% of common bean production in the world are grown in areas subjected to drought stress, and consequently results in a low level of average global yield production (Graham and Ranalli, 1997; Beebe et al., 2008).

In plants growing in dry soil, both shoot and root growth are hampered (Westgate and Boyerm 1985; Sharp et al., 1988) While an important feature of the root system response to soil drying is, the maintenance of root elongation at water potentials that are low enough to inhibit shoot growth completely (Sharp et al., 2004; Yamaguchi and Sharp, 2010), which facilitating water uptake from subsoil (Sponchiado et al., 1989; Serraj and Sinclair, 2002). Investigations on the spatial distribution of the response of root-elongation to drought indicated that the elongation was preferentially maintained at the root apex (Sharp et al., 2004; Yamaguchi and Sharp, 2010; Yamaguchi et al., 2010). Physiological studies on the response of the primary root growth of maize to water stress have demonstrated the involvement of three possible mechanisms: osmotic adjustment, modification of cell-wall (CW) extension properties and ABA accumulation (Sharp et al., 2004; Yamaguchi and Sharp, 2010). Water loss from the plant cells controls turgor pressure and so directly affects the extensibility of the plant CW (Moore et al., 2008). The effect of drought stress on CW structure and properties has been extensively studied in maize roots at physiological and molecular level (Wu and Cosgrove, 2000; Fan and Neumann, 2004; Sharp et al., 2004; Fan et al., 2006; Poroyko et al., 2007; Zhu et al., 2007; Spollen et al., 2008; Yamaguchi and Sharp, 2010).

Our previous physiological study demonstrated that the osmotic stress (OS, polyethylene glycol, PEG)-induced reduction of CW porosity enhanced Al resistance in common bean by the reduction of Al accumulation in the root tips (Yang et al., 2010), the main Al-sensitive root zone (Rangel et al., 2007). A transcriptomic analysis indicated that among the osmotic stress-regulated genes, CW synthesis and organization-related genes were mostly down-regulated, and the CW modification genes *XTH* (xyloglucan endotransglucosylase/hydrolase) and *BEG* (glucan endo-1,3-beta-glucosida or

beta-1,3-glucanase), and the structure protein hydroxyproline-rich glycoprotein (HRGP) were supposed to be involved in modification of CW porosity (Yang et al., 2011). However, transcriptomic profiling sometimes fails to unequivocally reveal the final functions of regulations of biological processes e.g. due to gene redundancy or post-translational modifications (Toorchi et al., 2009; Zörb et al., 2010). Post-translational modifications, such as phosphorylation and glycosylation, can result in a dramatic increase in proteome complexity without a concomitant increase in gene expression (Jensen, 2004; Rose et al., 2004; Jiang et al., 2007). Therefore, a proteomic and phosphoproteomic approach was performed in this study (i) to better understand the PEG-induced changes of osmotic stress and CW-related proteins in root tips of the common bean genotype VAX 1, and (ii) to further classify the potential mechanisms of CW proteins involved in the adjustment of wall porosity.

Materials and Methods

Plant materials and growing conditions

Seeds of common bean genotype VAX (Al-sensitive) were germinated on filter paper sandwiched between sponges. After three days, uniform seedlings were transferred to a continuously aerated simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ (Rangel et al., 2007). Plants were cultured in a growth chamber under controlled environmental conditions at 16/8 h light/dark cycle, 27/25 °C day/night temperature, 70% relative air humidity, and a photon flux density of 230 μmol m⁻² s⁻¹ of photosynthetically active radiation at mid plant height. The pH of the nutrient solution was gradually lowered to 4.5 within two days. Then the plants were transferred into a simplified nutrient solution (see above) without or with AlCl₃, PEG 6000 (Sigma-Aldrich Chemie GmbH, Steinheim, Germany). 1-cm root tips were harvested and immediately frozen in liquid nitrogen in Eppendorf vials for protein extraction. The osmotic potential (OP) of PEG 6000 (150 g L⁻¹) solution was -0.60 MPa, measured with a cryoscopic osmometer (Osmomat 030, Gonotec GmbH, Berlin, Germany).

Measurement of root-elongation rate

Two hours before the treatment was initiated tap roots were marked three centimetres behind the root tip using a fine point permanent marker (Sharpie blue, Stanford) which did not affect root growth during the experimental period. Afterwards, the plants were transferred into a simplified nutrient solution (see above) without or with PEG in the absence or presence of Al. Root elongation was measured after the treatment period using mm scale.

Determination of cell-sap osmotic potential

The root-tip cell-sap was extracted and measured according to Tabuchi et al. (2004) with modifications. After treating the plants with PEG (0 and 150 g L⁻¹) for 24 h, 30 root tips of 1 cm length were excised and transferred into micro-filtration tubes with a membrane pore size of 0.45 μm (GHP Nanosep MF Centrifugal Device, Pall Life Sciences, Ann Arbor, USA) in a 1.5 mL plastic tube after removing the free solution on the surface of roots by brief centrifugation. Then the samples were immediately frozen in liquid nitrogen and stored at -80 °C until use. The root tips were thawed at room temperature, and then

centrifuged at 5,000 g for 10 min at 4 °C. More than 50 µL cell sap was obtained from 30 root tips. The osmotic concentration of the cell sap was determined with a cryoscopic osmometer (Osmomat 030, Gonotec GmbH, Berlin, Germany), and the osmotic potential was calculated according to the van't Hoff equation (Nobel, 1991): $\pi = -nRT$, where π is the osmotic potential, R the gas constant, T the absolute temperature, and n the molar concentration.

Extraction of total soluble protein

Approximately 200 root tips of 1 cm length were harvested after treating the plants without or with 150 g L⁻¹ PEG for 24 h, and ground with mortar and pestle in liquid nitrogen. The homogenized sample powder was suspended in 4 mL extraction buffer (500 mM Tris, 50 mM EDTA, 100 mM KCl, 700 mM sucrose, 25 mM sodium fluoride, 1 mM sodium molybdate, 50 mM sodium pyrophosphate, 2% v/v β-mercaptoethanol and protease inhibitor (1 tablet/10 ml aliquots, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) and incubated for 10 min on ice. Afterwards, an equal volume of water-saturated phenol was added and incubated for another 10 min at room temperature on a rotary shaker. The aqueous and organic phases were separated by centrifugation for 10 min at 11,000 g and 4 °C. The phenolic phase was re-extracted with an equal volume of extraction buffer and centrifuged again. Phenol phases were combined and supplemented with 5 volumes of 0.1 M ammonium acetate in methanol and incubated overnight at -20 °C for protein precipitation. After centrifugation at 11,000 g for 3 min at 4 °C, precipitated proteins were washed three times with ammonium acetate in methanol and finally with acetone. Pellets were air-dried. Extracted proteins were redissolved in rehydration solution (see below) for 2-DE analysis. Protein concentration of extracts were determined in rehydration solution using the 2-D Quant Kit[®] (GE Healthcare, Munich, Germany) according to the manufacturer's instructions.

Extraction of apoplastic proteins

Apoplastic proteins were extracted from control (-PEG) and PEG-treated root tips of 1 cm length of bean genotype VAX 1 for 24 h, according to the methods described by Zhu et al. (2006). Approximately 2,000 root tips (1 cm length) were excised and transferred into 20 mM ice-cold K₂PO₄ solution (pH 6.0). The root tips were then rinsed twice with 0.01 M MES buffer and oriented vertically with the root apex at the top in a filter column with a membrane pore size of 0.45 µm (MACHEREY-NAGEL, Düren, Germany). The filter

column was placed into a vial and the whole assembly was held on ice. Twenty millilitres of ice-cold 0.01 M MES buffer (pH 5.5) containing 0.2 M KCl plus protease inhibitors (1 mM phenylmethylsulfonyl fluoride and 5 μ L of protease inhibitor cocktail; Sigma, Germany) were added to the vial submerging the plant tissue. The whole assembly containing the root tips was vacuum infiltrated at -50 kPa for 15 min and for another 5 min without vacuum. The vial was removed, drained, and excess buffer was blotted away from the root tips through the bottom of the filter column. The filter column with root tips were then transferred to a new vial and centrifuged for 15 min at 1,000 g. All steps were conducted on ice or in a cold room at 4 $^{\circ}$ C. Infiltration and centrifugation were then repeated twice. Apoplastic extracts of resulting three fractions were combined in Vivaspin 6 Centrifugal Concentrators (5,000 MWCO PES, VIVASCIENCE, UK) and centrifuged for 2 h at 5,000 g. Precipitation of apoplastic proteins was done as described in previous section.

In each fraction of apoplastic protein extracts, the activity of malate dehydrogenase (MDH), a commonly accepted marker for cytosolic contamination, was assayed according to Bergmeyer and Bernt (1974) and the protein yield was quantified according to the method of Bradford (1976).

Two dimensional isoelectric focusing (2D IEF) / sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE)

IEF/SDS-PAGE was carried out as described by Fühns et al. (2008). Basically an IPGphor system (GE Healthcare, Munich, Germany) and immobiline DryStrip gels (18 cm) with a nonlinear pH gradient of 3-11 (for total soluble and apoplastic proteins) or 4-7 (for total soluble phosphoproteins) were used. Proteins (about 1,000 μ g and 80 μ g for total and apoplastic soluble proteins, respectively) were dissolved in rehydration solution (8 M urea, 2% w/v CHAPS, 0.5% v/v carrier ampholyte mixture (IPG bufferm pH 3-11 or 4-7 NL; GE Healthcare), 50 mM dithiothreitol, 12 μ L/mL DeStreak (GE Healthcare) and a trace of bromophenol blue) and loaded onto individual gel strips. Focussing was done according to Werhahn and Braun (2002). Afterwards, the focused IPG strips were incubated with equilibration solution (50 mM Tris-HCl (pH 8.8), 6 M urea, 30% v/v glycerol, 2% w/v SDS and bromophenol blue) supplemented with (i) 1% w/v dithiothreitol and (ii) 2.5% w/v iodoacetamide each for 15 min. Then the strips were placed horizontally onto second dimension SDS gels and proteins were separated according to Schägger and von Jagow (1987). Afterwards, for total soluble and apoplastic proteins, 2-D gels were stained with

colloidal Coomassie-blue (CBB)-G250 according to Neuhoff et al. (1985, 1990).

For phosphoprotein detection, 2D gels were stained with a modified protocol using Pro-Q Diamond Phosphoprotein Stain (Pro-Q DPS; Molecular Probes) according to Agrawal and Thelen (2009). Following image acquisition gels stained with Pro-Q DPS-stained gels, the gels were stained with CBB-G250 to detect total proteins (Neuhoff et al., 1985; 1990). In each treatment of the independent experiment, three biologically independent replicates were performed.

Image acquisition, image analysis and statistical analysis

Image acquisition of coomassie-stained gels was done using an Epson Expression 1600 scanner (Epson, Mehrbusch, Germany) at 300 dpi. Resolutions were stored as TIFF files. Phosphoprotein detection on gels was done using a TyphoonTM Variable Mode Imager using 532 nm excitation and 580 nm bandpass emission filter at 100 μm resolution. Images were stored as 16-bit TIFF files (Agrawal and Thelen, 2009). 2-D gel image analysis of coomassie and for phosphoproteins stained gels was carried out using ImageMasterTM 2D Platinum Software 6.0 (GE Healthcare). To compensate the variability due to sample loading, gel staining and destaining, the spot volume was normalized as relative volume, dividing each spot volume value by the sum of the total spot volume of the corresponding gel. In this study, significantly changed proteins between control and treatment were defined as proteins which were more or less abundant by a factor of 1.5 or 0.67, respectively, with $P \leq 0.05$ (Student's t-test) unless otherwise specified.

Mass spectrometric analysis and data interpretation

After manually picking of protein spots with changed abundance each spot was dried under vacuum. In-gel digestion was performed with an automated protein digestion system, MassPREP Station (Micromass, Manchester, UK). The gel slices were washed three times in a mixture containing 25 mM NH_4HCO_3 :acetonitrile (1:1, v/v). The cysteine residues were reduced by 50 μL of 10 mM dithiothreitol at 57 $^\circ\text{C}$ and alkylated by 50 μL of 55 mM iodacetamide. After dehydration with acetonitrile, the proteins were cleaved in the gel with 40 μL of 12.5 $\text{ng } \mu\text{L}^{-1}$ of modified porcine trypsin (Promega, Madison, WI, USA) in 25 mM NH_4HCO_3 at room temperature for 14 h. The resulting tryptic peptides were extracted with 60% acetonitrile in 0.5% formic acid, followed by a second extraction with 100% (v/v) acetonitrile.

Nano-LC-MS/MS analysis of the resulting tryptic peptides was performed using an Agilent 1100 series HPLC-Chip/MS system (Agilent Technologies, Palo Alto, USA) coupled to an HCT Ultra ion trap (Bruker Daltonics, Bremen, Germany). Chromatographic separations were conducted on a chip containing a Zorbax 300SB-C18 (75 μm inner diameter \times 150 mm) column and a Zorbax 300SB-C18 (40 nL) enrichment column (Agilent Technologies).

HCT Ultra ion trap was externally calibrated with standard compounds. The general mass spectrometric parameters were as follows: capillary voltage, -1750 V ; dry gas, 3.0 L min^{-1} ; dry temperature, $300\text{ }^{\circ}\text{C}$. The system was operated with automatic switching between MS and MS/MS modes. The MS scanning was performed in the standard-enhanced resolution mode at a scan rate of 8100 m/z s^{-1} with an aimed ion charge control of 100,000 in a maximal fill time of 200 ms and a total of four scans were averaged to obtain a MS spectrum. The three most abundant peptides and preferentially doubly charged ions were selected on each MS spectrum for further isolation and fragmentation. The MS/MS scanning was performed in the ultrascan resolution mode at a scan rate of $26,000\text{ m/z s}^{-1}$ with an aimed ion charge control of 300,000 and a total of six scans were averaged to obtain an MS/MS spectrum. The complete system was fully controlled by ChemStation Rev. B.01.03 (Agilent Technologies) and EsquireControl 6.1 Build 78 (Bruker Daltonics) softwares. Mass data collected during LC-MS/MS analyses were processed using the software tool DataAnalysis 3.4 Build 169 and converted into .mgf files. The MS/MS data were analyzed using the MASCOT 2.2.0. algorithm (Matrix Science, London, UK) to search against an in-house generated protein database composed of protein sequences of Viridiplantae downloaded from <http://www.ncbi.nlm.nih.gov/sites/entrez> (on 6 March 2008) concatenated with reversed copies of all sequences (23 478 588 entries). Spectra were searched with a mass tolerance of 0.5 Da for MS and MS/MS data, allowing a maximum of one missed cleavage by trypsin and with carbamidomethylation of cysteines, oxidation of methionines, and N-terminal acetylation of proteins specified as variable modifications. Protein identifications were validated when at least two peptides with high quality MS/MS spectra (Mascot ion score greater than 31) were detected. In the case of one-peptide hits, the score of the unique peptide must be greater (minimal 'difference score' of 6) than the 95% significance Mascot threshold (Mascot ion score >51). For the estimation of the false positive rate in protein identification, a target-decoy database search was performed (Elias and Gygi, 2007).

Protein identifications by MS only were carried out for one of the three gel replicates,

because gels obviously were very similar. Also, all analyses allowed to unambiguously identify proteins of the expected molecular mass range.

Statistical analysis

A completely randomized design was used, with four to twelve replicates in each experiment. If not mentioned otherwise, statistical analysis was carried out using SAS 9.2. Means were compared using t or Tukey test depending on the number of treatments being compared. *, **, *** and ns denote significant differences at $P < 0.05$, 0.01, 0.001, and not significant, respectively.

Results

Root elongation rate of bean genotype VAX 1 was inhibited by 31% by a 24-h exposure to 150 g L⁻¹ PEG (pH 4.5) in the simplified nutrient solution (Fig. 1A). Since cell expansion is determined by osmotic potential as well as CW extensibility in the root cells and osmotic adjustment plays a major role in plant adaptation to osmotic stress (OS), the osmotic potential of the root cells was examined using an osmometer. The osmotic potential of the cell sap of the root tips was decreased by 24-h treatment with 150 g L⁻¹ PEG from -0.55 to -0.96 MPa (Fig. 1B), suggesting osmotic adjustment of root cells by accumulating osmolytes facilitating water uptake into cells and thus adaptation to the PEG-induced osmotic stress.

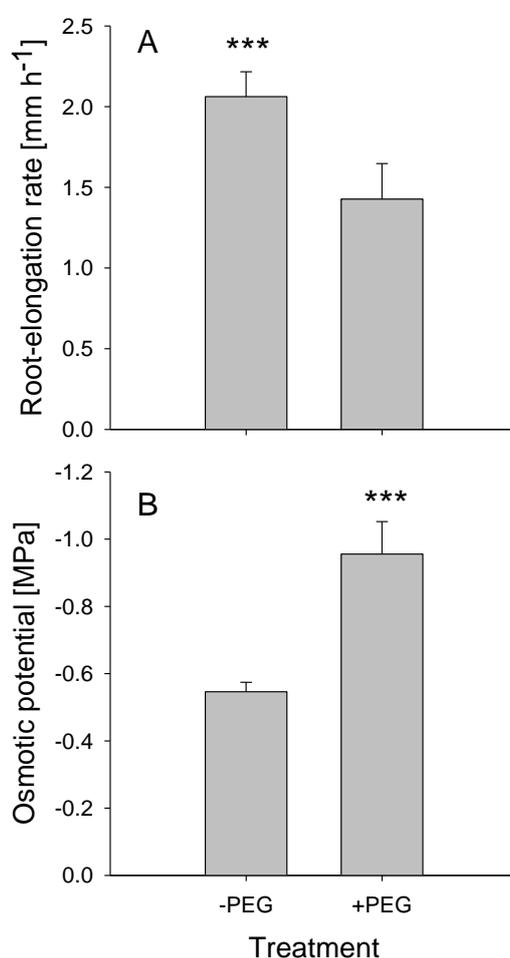

Figure 1 Root-elongation rate (A) and cell sap osmotic potential (B) of 1-cm root tips of the common bean genotype VAX 1 under osmotic stress (0, -0.60 MPa OP). Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ for 48 h for acclimation and pH adaptation, and then treated without or with PEG (150 g L⁻¹) in the simplified nutrient solution for 24 h, pH 4.5. Bars represent means ± SD, n = 12 for (A) and n = 4 for (B). *** denote significant differences at $P < 0.001$.

To identify the proteins affected by short-term (24 h) PEG-induced osmotic stress, the total soluble proteins were extracted from control (- PEG) and PEG-treated root tips. A total of 716 spots were detected after 2D IEF/SDS PAGE and CBB staining. Using specific threshold parameters (see Materials and Methods section), twenty two proteins were identified exhibiting differential abundance due to the PEG treatment (Fig. 2). Nine of these proteins showed higher abundance in PEG-treated roots and thirteen proteins showed higher abundance in control (- PEG) roots (Fig. 2). Close-ups of gel regions containing proteins of differential abundance are shown in Fig. 3.

The twenty two differentially expressed proteins were analyzed by *de novo* peptide sequencing using ESI MS/MS and identified by sequence comparisons using the NCBI protein database (Table 1). The identified twenty two proteins were classified according to their proposed biological functions using the UniProt database (Table 1; Fig. 4). Among the nine increased proteins the functional categories carbohydrate metabolism, amino acid metabolism, protein processing, transcription and unknown were represented by 45%, 22%, 11%, 11% and 11%, respectively. Among the thirteen decreased proteins (showed in Table 1) the functional categories carbohydrate metabolism, amino acid metabolism, other metabolisms, stress response/defence and protein processing were represented by 38%, 31%, 15%, 8% and 8%, respectively. The functional classification of the identified increased and decreased proteins showed that most of the proteins (77%) were involved in pathways of the primary metabolism (acetoacetyl-CoA thiolase, fructokinase, myo-inositol 1-phosphate synthase, phosphoglycerate mutase, fructokinase-like protein, alcohol dehydrogenase Adh-1, enolase and NADPH-specific isocitrate dehydrogenase in carbohydrate metabolism; S-adenosylmethionine synthetase, D-3-phosphoglycerate dehydrogenase, methionine synthase in amino acid metabolism), showing the importance of the primary metabolism in the response and adaptation of root tips to PEG-induced OS.

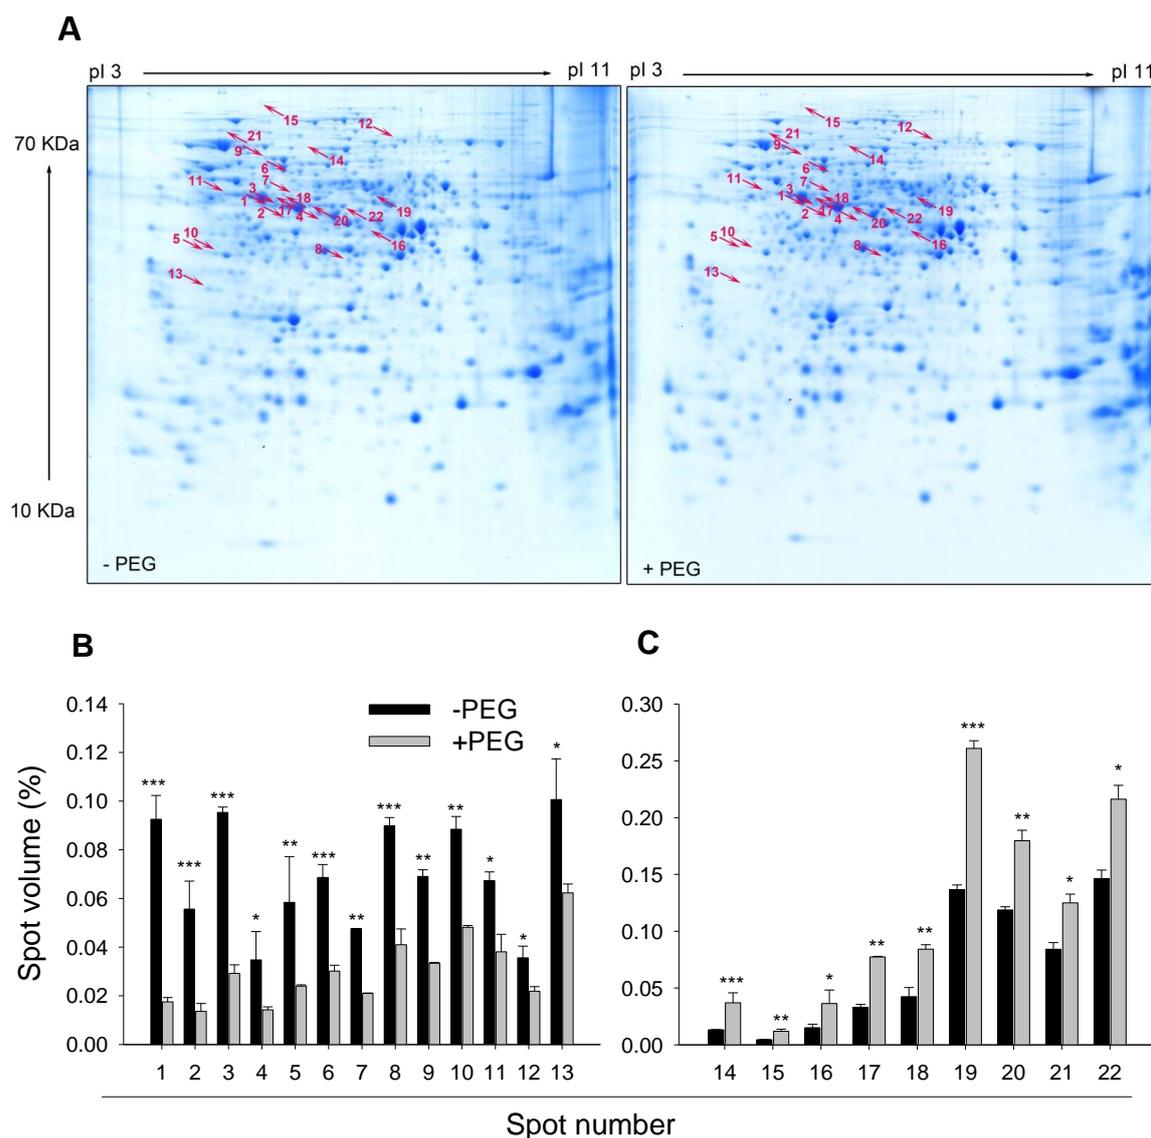

Figure 2 Representative Coomassie-stained 2D IEF/SDS-PAGE gels of the total soluble proteins (A) and the relative spot volumes of the 22 significantly decreased (B) and increased (C) protein spots in the control (-PEG) and PEG-treated root tips of common bean genotype VAX 1. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, and then treated without or with PEG (150 g L^{-1}) in the simplified nutrient solution for 24 h, pH 4.5. Proteins were extracted from the root tips, separated by 2D IEF/SDS-PAGE, and stained by CBB. Treatment-affected spots were marked by arrows and numbered consecutively. Three biological replications of each treatment were analyzed using the Image MasterTM 2D PLATINUM Software 6.0. In (B) and (C), bars represent means \pm SD, $n = 3$ and *, ** and *** denote significant treatment differences between means at $P < 0.05$, 0.01 and 0.001, respectively.

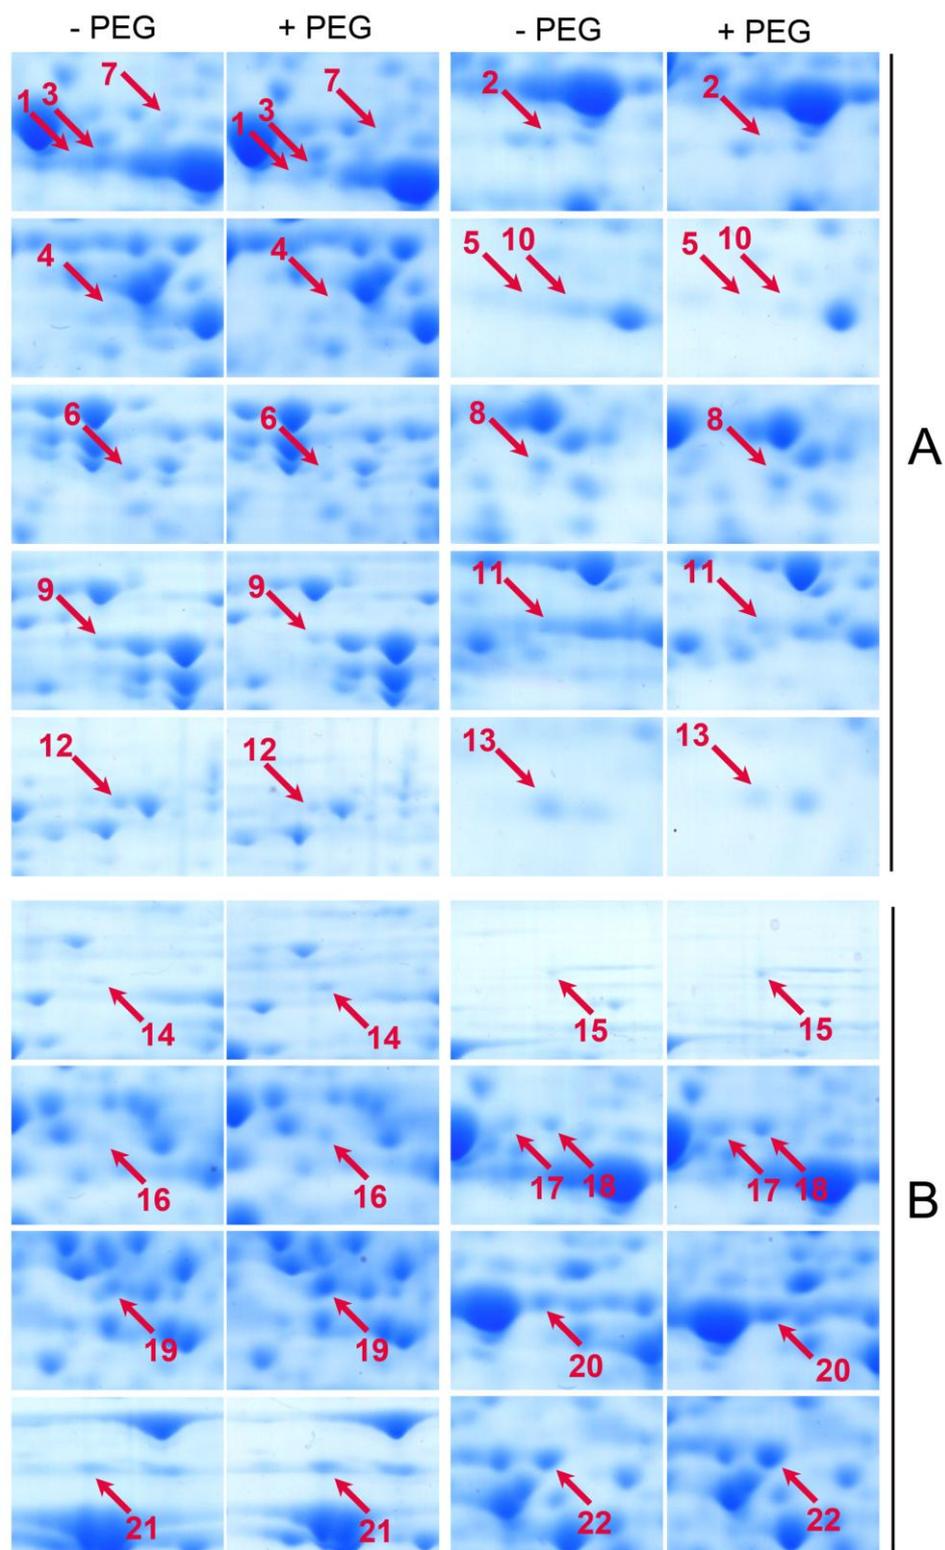

Figure 3 Close-ups of significantly decreased (A) and increased (B) protein spots in response to PEG in the root tips of common bean genotype VAX 1. The Coomassie-stained 2D IEF/SDS-PAGE gels of the total soluble proteins are shown in Fig. 2.

Table 1 The list of the 22 proteins with significantly different abundance in the root tips of common bean genotype VAX 1 in response to PEG. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ for 48 h for acclimation and pH adaptation, and then treated without or with PEG (150 g L⁻¹) in the simplified nutrient solution for 24 h, pH 4.5. These 22 protein spots were shown in the Coomassie-stained 2D IEF/SDS-PAGE gels of Fig. 2 and Fig. 3. Spot No.: corresponding to the spots number of Figure 2 and Figure 3. FC: fold change (the relative protein spot volume of +PEG treatment to the relative protein spot volume of -PEG treatment). The proteins were identified by nano LC-MS/MS and BLASTed in NCBI database. The protein functions were categorized based on the UniProt database and KEGG pathway.

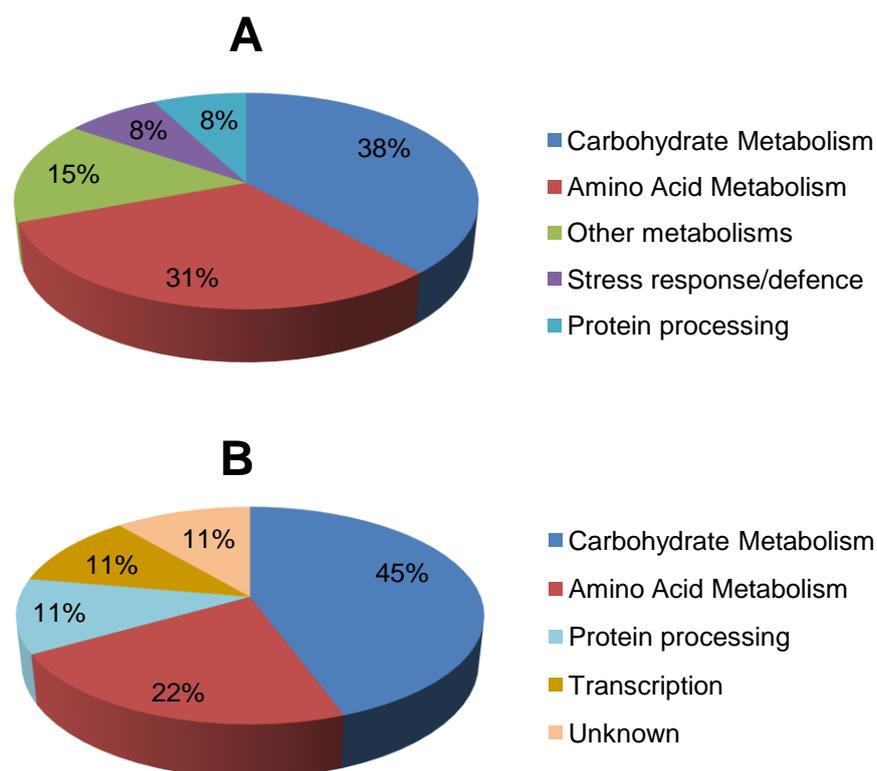

Figure 4 Functional categories of the 22 significantly decreased (A) and increased (B) proteins in response to PEG in the root tips of common bean genotype VAX 1. The identifications of these 22 proteins by nano LC-MS/MS are shown in Table 1.

To investigate the effect of OS on the regulation of CW proteins of root tips of common bean, soluble and ionically bound apoplastic proteins were extracted and analysed. First we tested the capability and efficiency of KCl as an extractant of CWPs from root tips of common bean. Different concentrations were tested for their effect on CWP yield and cytosolic protein contamination (CPC). The CPC was assessed by assay of malate dehydrogenase (MDH) activity (Table 2). Cell-wall proteins extracted with 0.1 M KCl did not show CPC in each of three sequential extractions, however, the protein yield was low. Infiltration with 0.4 M KCl yielded a great amount of protein, but also resulted in a high CPC in the first infiltration step (data not shown). Therefore, to obtain the maximum protein yield with minimum CPC, 0.2 M KCl was chosen for extracting CWPs from PEG-treated root tips of common bean. This KCl concentration of 0.2 M has been previously used to extract CWPs from the root elongation zone of maize (Zhu et al., 2006).

Compared to the residues of proteins (tightly, non-extractable apoplastic proteins and symplastic proteins), the MDH activity in the apoplastic and CW loosely bound proteins is low (Table 2), indicating only little contamination. PEG treatment (150 g L^{-1}) reduced the extracted apoplastic protein yield in the root tips (Table 2).

2D IEF/SDS PAGE and subsequent staining with CBB showed that individual proteins could be visualized in spite of the low amount of CW proteins ($80 \text{ }\mu\text{g}$) loaded on each gel (Fig. 5). On average, a total of 171 spots was detected on gels containing proteins extracted from PEG-treated and control (- PEG) root tips. A total of thirteen proteins were significantly affected by PEG-induced OS. Of these, five and eight proteins showed lower and higher abundance in PEG-treated root tips, respectively (Fig. 5). ESI MS/MS analysis of these thirteen spots allowed the identification of eight proteins by BLAST search at the NCBI protein database (Tab. 3). Two of the proteins (fructokinase and pathogenesis-related protein 1) were reduced and six proteins (beta xylosidase, pectinacetyltransferase precursor, serine hydroxymethyltransferase, serine carboxypeptidase and fructose-1,6-bisphosphate aldolase) increased in abundance by PEG-induced OS (Table 3). Close-ups of the gels are shown in Supplemental Fig. S1.

Table 2 Yield of 0.2 mM KCl-extractable apoplastic proteins and their MDH activity (indicator of cytosolic contamination) from 1-cm root tips of common bean genotype VAX 1 grown in absence and presence of PEG 6000 for 24 h. Root tips were three times consecutively infiltrated. The residue included tightly, non-extractable apoplastic proteins and symplastic proteins.

PEG treatment [g/L]	Infiltration step	Protein yield [ng (1-cm root tip) ⁻¹]	MDH Activity [nmol min ⁻¹ (1-cm root tip) ⁻¹]

The PEG-induced changes of phosphorylated and de-phosphorylated proteins in root tips were examined by a phosphoproteomic approach using 2D IEF/SDS PAGE and Pro-Q DPS staining. Out of the identified ten significantly changed proteins, seven showed increased phosphorylation (glucose-6-phosphate isomerase, actin, dehydrin and lactoylglutathione lyase) and three proteins decreased phosphorylation (Ser/Thr-specific protein phosphatase 2A, regulatory subunit beta isoform, pyruvate kinase and branched-chain amino acid aminotransferase) by PEG-induced OS (Fig. 6; Table 4). Close-ups of three of these proteins with high abundance are shown in Fig. 6B and were identified as belonging to the same protein family, dehydrin. The close-ups of all differentially formed proteins in response to PEG treatment are presented in Supplemental Fig. S2.

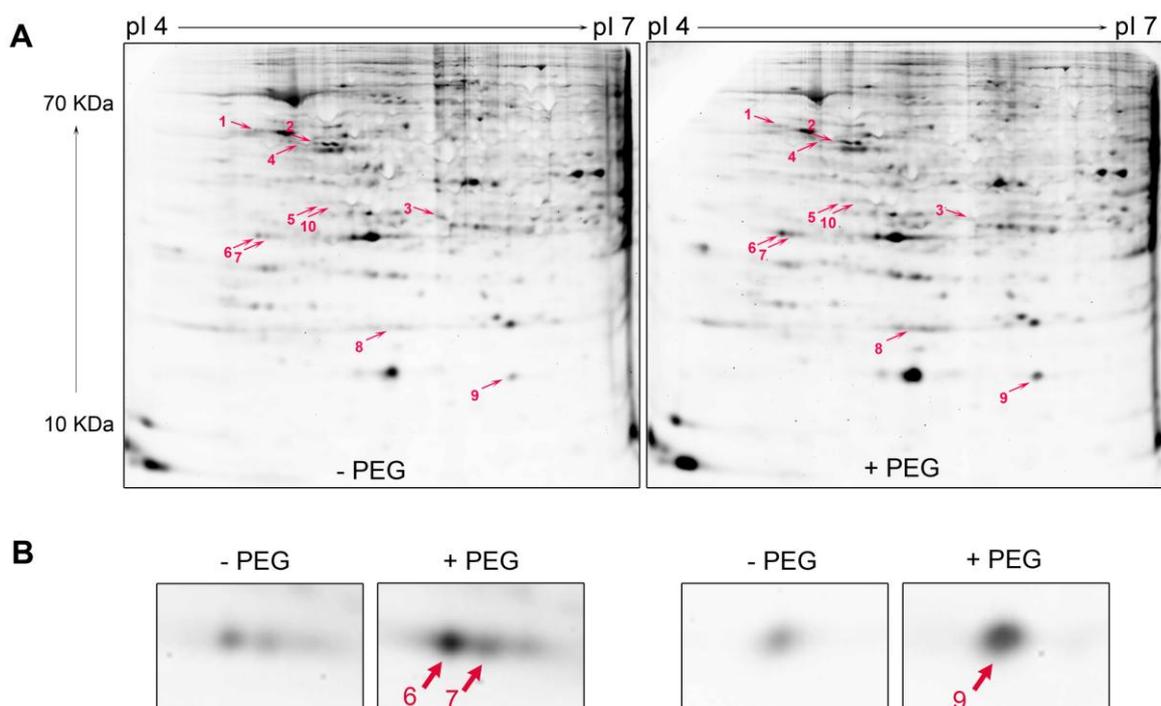

Fig. 6 Representative Pro-Q DPS-stained 2D IEF/SDS-PAGE gels of the total soluble proteins in the control (- PEG) and PEG-treated root tips of common bean genotype VAX 1 (A) and three magnified spots with high protein abundance (B). Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, and then treated without or with PEG (150 g L^{-1}) in the simplified nutrient solution for 24 h, pH 4.5. Proteins were extracted from the root tips, separated by 2D IEF/SDS-PAGE, and stained by Pro-Q DPS. Treatment-affected spots were marked by arrows and numbered consecutively. Three biological replications of each treatment were analyzed using the Image MasterTM 2D PLATINUM Software 6.0.

Table 4 List of ten phosphoproteins with significantly different abundance in the root tips of common bean genotype VAX 1 in response to PEG. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ for 48 h for acclimation and pH adaptation, then treated without or with PEG (150 g L⁻¹) in the simplified nutrient solution for 24 h, pH 4.5. These 10 phosphoprotein spots are shown in the Pro-Q DPS-stained 2D IEF/SDS-PAGE gels of Fig. 6 and in supplemental Fig. 2. Spot No. : corresponding to spot number of Fig. 6 and supplemental Fig. 2. FC: fold change (the relative protein spot volume of +PEG treatment to the relative protein spot volume of -PEG treatment). The proteins were identified by nano LC-MS/MS and BLASTed in NCBI database.

Discussion

Physiological osmotic adjustment and modification of cell-wall (CW) extensibility were suggested as two major mechanisms involved in the maintenance of root elongation during water deficit (Sharp et al., 2004; Yamaguchi and Sharp, 2010). In this study, functional categorization of total soluble proteins showed that the majority of the affected proteins were involved in primary metabolism (Fig. 4; Table 1), particularly carbohydrate (acetoacetyl-CoA thiolase, fructokinase, myo-inositol 1-phosphate synthase, phosphoglycerate mutase, fructokinase-like protein, alcohol dehydrogenase Adh-1, enolase and NADPH-specific isocitrate dehydrogenase) and amino acid (S-adenosylmethionine synthetase, D-3-phosphoglycerate dehydrogenase, methionine synthase) metabolism, confirming the important role of accumulation of carbohydrates and soluble amino acids involved in osmotic adjustment (Morgan, 1984). On the other hand, protein synthesis and modification of carbohydrates regulated by the proteins involved in metabolic pathways, may facilitate the adjustment of CW synthesis and extensibility, and thus the regulation of root elongation. Also, some proteins were supposed to play key roles in the protection against OS-induced severe physical destruction of CW integrity, such as dehydrin (Layton et al., 2010), which was highly significantly up-regulated by OS in this study. Therefore, based on the above information, the discussion below will particularly focus on the carbohydrate and amino acid metabolism and on CW-related proteins.

The osmotic adjustment in the growing root region in response to OS can in part result from increased net accumulation rates of osmotic solutes. Physiological factors influencing such accumulation rates are solute synthesis, uptake, catabolism and utilization. All of these represent adaptive responses contributing to growth maintenance (Sharp et al., 2004). It has been reported that OS increased sugar (e.g. fructose, glucose and sucrose) accumulation in roots of mung bean (*Vigna mungo*) seedlings (Itoh et al., 1987) and the tropical tree *Colophospermum mopane* (Johnson et al., 1996). Fructokinase specifically catalyzes the transfer of a phosphate group from ATP to fructose, thereby activating this sugar for further metabolic processes. In this study, OS-induced reduced abundance of fructokinase in the root tips of common bean (Fig. 2; Fig. 3; Table 1) may lead to fructose accumulation and in this sense may be regarded as part of osmotic adjustment. Indeed, also in soybean roots Toorchi et al. (2009) found by proteomic analysis that PEG-induced OS reduced the formation of a fructokinase 2 protein.

In *Arabidopsis*, Hummel et al. (2010) found that organic acids in addition to K⁺ are main

contributors to osmotic adjustment under water deficit conditions. We previously reported that PEG-induced OS increased citrate, malate, cis-aconitate and fumarate contents in root tips of common bean (Yang et al., 2010) indicating a major role of the accumulation of these organic acids in osmotic adjustment. The isocitrate dehydrogenase is an enzyme that participates in the citric acid cycle. It catalyzes oxidative decarboxylation of isocitrate to alpha-ketoglutarate and requires either NAD^+ or NADP^+ , producing NADH and NADPH, respectively. It was thought (Chen and Gadgil, 1990) that citrate in the cytosol is first converted to isocitrate by the action of aconitase, and then to 2-oxoglutarate by the action of NADP-specific isocitrate dehydrogenase (NADP-ICDH). Subsequently, 2-oxoglutarate is utilized as carbon skeleton for the glutamine synthase/glutamate synthase pathway. Thus a decrease of NADP-ICDH activity was associated with the accumulation of citrate in the plant tissue (Sadka et al., 2000; Kihara et al., 2003). In contrast, in the present study it was found that osmotic stress increased the expression of NADPH-specific ICDH in root tips of common bean (Fig. 2; Fig. 3; Table 1) not supporting the hypothesis that increased accumulation of citrate in the cytosol is a consequence of reduced activity NADP-ICDH (Massonneau et al. 2001, Anoop et al., 2003, Rangel et al., 2010). However, on the other hand enhanced formation of NADPH-specific ICDH due to OS may increase the accumulation of citrate in root tips through increasing citric acid cycle turnover. Moreover, it may be involved in defense processes, since NADP-ICDH was shown to play an important role in cellular defense against stress-induced oxidative injury (Jo et al., 2002; Lee et al., 2002). Liu et al. (2010) found that an isolated cDNA encoding cytosolic NADP-dependent ICDH from maize conferred salt tolerance to Arabidopsis.

Phosphoglycerate mutase (PGM) is a glycolytic enzyme, which catalyzes the conversion of 3-phosphoglycerate to 2-phosphoglycerate. Ergen et al. (2009) found that the expression of the gene encoding PGM in leaves of wild durum wheat (*Triticum turgidum*) was promoted while in roots it was suppressed during dehydration. Mazarei et al. (2003) observed that an *AtPGM* gene in Arabidopsis was localized in the shoot and root meristems, of which the expression was down-regulated by ABA. However, the function of this protein in stress responses remains to be elucidated. Myo-inositol 1-phosphate synthase (MIPS) catalyzes the rate-limiting step in the synthesis of myo-inositol. It was reported that *mips1* mutants resulted in lowered myo-inositol levels and enhanced cell death in Arabidopsis (Meng et al., 2009; Donahue et al., 2010). Moreover, Donahue et al. (2010) provided evidence that *mips1* mutants had increased sensitivity to ABA and OS (salt and sorbitol treatment), which could be rescued by myo-inositol supplementation. The

OS-induced suppression of MIPS in this study (Fig. 2; Fig. 3; Table 1) suggests that the root tips of common bean suffered severe stress causing cell damage through lowered *myo*-inositol abundance. Enolase is responsible for the conversion of 2-phosphoglycerate to phosphoenolpyruvate, which is involved in glycolysis. Enolase was detected in the CWs of *Candida albicans*, *Arabidopsis thaliana*, *Medicago sativa*, and *Zea mays* (Chivasa et al., 2002; Pitarch et al., 2002; Watson et al., 2004; Zhu et al., 2006). Using immunolocalization, enolase was shown to be secreted to the cell wall or the extracellular space even though it lacked a signal peptide (Edwards et al., 1999). In this study, the abundance of enolase was enhanced by PEG treatment (Fig. 2; Fig. 3; Table 1). The role of overexpression of enolase under osmotic stress remains unclear.

Some proteins involved in amino acid biosynthesis were differentially affected in abundance by OS in this study, such as S-adenosylmethionine synthetase (methionine adenosyltransferase, SAMS), methionine synthase (MetS) and D-3-phosphoglycerate dehydrogenase (PHGDH) (Fig. 1; Fig. 2; Table 1). MetS catalyzes the final step in methionine biosynthesis and SAMS catalyzes the conversion of ATP and methionine into S-adenosylmethionine (SAM) (Ravanel et al., 1998). SAM serves as a cofactor in a variety of biochemical reactions in all living organisms. It acts as a methyl donor to proteins, lipids, polysaccharides, nucleic acids (Tabor and Tabor 1984), participates in cell-wall lignin-synthesis (Sederoff and Chang 1991), and mediates the biosynthesis of ethylene (Yang and Hoffman, 1984; Kende 1993). Also, SAM is believed to play a regulatory role in synthesis of methionine and other aspartate-derived amino acids (Peleman et al., 1989). Manavella et al. (2006) demonstrated that overexpression of the sunflower (*Helianthus annuus*) HD-Zip protein subfamily 1 member *Hahb-4* transcription factor in *Arabidopsis thaliana* improved desiccation tolerance via the repressing of SAMS transcription and 1-aminocyclopropane-1-carboxylate oxidase, and subsequently suppressed the biosynthesis of ethylene. Ingram and Bartels (1996) reported that drought-caused alterations in the chemical composition and physical properties of the CW (e.g. CW extensibility) may involve genes encoding SAMS. Under non-stressed conditions, higher expression of SAMS genes correlated with the extent of lignification of tissues in *Arabidopsis* (Peleman et al., 1989). Lignification of CW by methylation of lignin monomers was described as one mechanism to avoid water loss under dehydration (Bhushan et al., 2007). Indeed, it has been reported that water deficit intensified the lignifications of root-tip cell-walls in maize (Fan et al., 2006) and soybean (Yamaguchi et al., 2009). Moreover, it has been suggested that cellular levels of SAM were regulated by MetS activity forming methionine, a

precursor of SAM (Ravanel et al., 1998, 2004). Therefore, the induction of MetS transcripts suggests an increased production of methionine and lignin methylation by SAM. Recent results confirmed that SAMS was involved in tolerance to abiotic stresses such as salinity stress (Sanchez-Aguayo et al., 2004; Jiang et al., 2007) and drought stress (Toorchi et al., 2009; Pandey et al., 2010). In this study PEG treatment led to increased abundance of a MetS (spot 21 in Fig. 1; Fig. 2 and Table 1) and SAMS (spot 20 in Fig. 1; Fig. 2 and Table 1), while the amount of another three SAMS proteins (spot 1, 2, 3 in Fig. 1; Fig. 2 and Table 1) in the root tips was repressed. The PEG-induced differential regulation of SMS proteins may be indicative for different isoforms of this protein. Under OS conditions the increase of SAMS may either improve lignification of root tips CW or increase biosynthesis of ethylene, while down-regulation of SMS may be caused by a changed demand for more methyl groups for lignin methylation (Bhushan et al., 2007). It has been reported that transcriptome and proteome levels of SAMS are down-regulated by OS (Seki et al., 2002; Yan et al., 2005; Jiang et al., 2007; Toorchi et al., 2009).

Sharp et al. (2004) suggested that in maize the extent of osmotic adjustment in the primary root tip, although substantial, was insufficient to maintain turgor comparable to well-watered levels in roots growing under severe drought. This was assessed directly by measuring the spatial distribution of turgor using a cell-pressure probe, which showed that turgor was reduced by over 50% throughout the root elongation zone of roots growing at a water potential of -1.6 MPa compared with well-watered control plants (Spollen and Sharp, 1991). Thus, enhancement of CW extensibility may contribute to the maintenance of root elongation in the apical region of water-stressed roots (Sharp et al., 2004; Yamaguchi and Sharp, 2010). Under multiple abiotic stress conditions, we recently found that osmotic stress-induced reduction of CW porosity could improve Al resistance by restricting Al accumulation in the apoplast of common bean root tips (Yang et al., 2010). Also by means of a transcriptome analysis we indentified some genes encoding proteins involved in CW modification (xyloglucan endotransglucosylase/hydrolase, XTH) and CW structure (hydroxyproline-rich glycoproteins, HRGPs), which were supposed to play major roles in PEG-mediated decrease of CW porosity (Yang et al., 2011). Several CW proteins/enzymes are believed to play roles in modifying the wall structure and controlling wall extension. These include expansin, XTH, and glucanases (Wu and Cosgrove, 2000; Bray, 2004; Sharp et al., 2004; Moore et al., 2008). Therefore, we aimed at identifying these proteins and to clarify their response to PEG treatment by extracting apoplastic and loosely ionically bound proteins in root tips of common bean and separating them by protein electrophoresis

techniques. Unlike what we expected, only a low protein yield was obtained by a fractional infiltration method. In addition, the extracted apoplastic protein yield in each infiltration step was reduced in PEG-treated roots (Table 2), further supporting that PEG-induced OS reduced CW porosity thereby reducing exchangeability of these proteins by extractants. Thus, proteins with high molecular weight could not be exchanged so that predominantly small molecular proteins were identified in this study. Although Zhu et al. (2007) identified a large amount of water deficit-induced CW proteins in maize using the same extraction procedures employed in the current study, the type I CW of common bean is different from type II CW of maize: the former contains higher pectic polysaccharides (Carpita and Gibeaut, 1993), which is the main factor determining CW porosity (Baron-Epel et al., 1988).

In spite of this, thirteen PEG-induced differentially affected proteins in the CW were obtained and eight of them were detected by MS analysis (Fig. 3; Table 3). The OS-induced reduction of fructokinase was also found in the CW fraction. It has been suggested that fructose formed from sucrose cleavage could be directly and rapidly converted into UDP-glucose via the hexose-phosphate pool (i.e. fructose-6-phosphate \rightleftharpoons glucose-6-phosphate \rightleftharpoons glucose-1-phosphate), and subsequently apoplastically provided for synthesis of CW polysaccharides (Konishi et al., 2004). Thus, it appears that a decrease of fructokinase may result in a reduction in CW polysaccharide content in root tips impeding root growth under OS, since fructokinase catalyzes the transfer of fructose into fructose-6-phosphate. Similar conclusions have been drawn by Toorchi et al. (2009). Indeed, Odanaka et al. (2002) reported that suppression of the gene *Frk2* encoding fructose kinase inhibited root growth of tomato. In sum, fructokinase may play a role in regulation of the energy metabolism, (1) possibly by providing fructose-6-phosphate for glycolysis and/or (2) through conversion to UDP-glucose (UDPG) to support biosynthesis of CW material (Karni and Aarni, 2002).

Fructose-1,6-bisphosphate aldolase reversibly catalyzes the conversion of fructose-1,6-bisphosphate to glyceraldehyde-3-phosphate. The extracellular matrix proteome analysis revealed that fructose-1,6-bisphosphate aldolase was indeed a CW protein which was increased during dehydration stress in chickpea (*Cicer arietinum*) (Bhushan et al., 2007) and rice (*Oryza sativa*) (Pandey et al., 2010) corroborating results of this study showing that PEG-induced apoplastic dehydration increased the abundance of apoplastically localized fructose-1,6-bisphosphate aldolase in root tips of common bean (Fig. 5; Table 3). Enhanced synthesis of fructose-1,6-bisphosphate aldolase was also

reported as response to salt stress in rice (Abbasi and Komatsu 2004) and mangrove plant *Bruguiera gymnorhiza* (Tada and Kashimura, 2009). Enhanced formation of fructose-1,6-bisphosphate aldolase may increase the flow of carbon through the Calvin cycle and lead to C-skeleton production for subsequent increased carbon flux through glycolysis. These traits would also lead to osmolyte production and contribute to OS tolerance.

Pathogenesis-related proteins (PRs) are mainly involved in the defense against pathogenic constraints and in general adaptation to stressful environments. The CW was the major accumulation site of these PRs (Edreva, 2005). Up to now, the biochemical function of PR1 is not known. However, suppression of PR 1 by OS (Fig.5; Table 3) in this study may reflect lower protection level and severe root-cell damage. Beta xylosidase was found in the stock of pathogen-degrading enzymes (Tezuka et al., 1993). A gene, *AtBLX1*, encoding beta xylosidase in Arabidopsis was proposed to be involved in secondary CW hemicellulose metabolism and plant development (Goujon et al., 2003). In contrast to our results showing PEG-mediated increased abundance of beta xylosidase in the CW of bean root tips (Fig. 5; Table 3), Zhu et al. (2007) found that water deficit reduced beta xylosidase in the apical 3-7 mm region of the maize primary roots. The exact function of beta xylosidase in response to osmotic/drought stress remains to be elucidated. In addition, the amount of pectin acetyltransferase, serine hydroxymethyltransferase, and serine carboxypeptidase was enhanced by osmotic stress, but the role of them in OS is not yet known.

Phosphoproteomics revealed that three proteins showed reduced and seven proteins increased phosphorylation by OS. Out of these, dehydrin underwent significantly enhanced phosphorylation by OS (Fig. 6; Table 4), while no PEG-effect in abundance of dehydrin by CBB-staining (data not shown) has been found indicating that the activation of dehydrin during OS by phosphorylation may play an important role in root responses to OS. Dehydrins are the second biggest group of late embryogenesis abundant proteins, which are well known to play crucial roles in cellular dehydration tolerance (Ingram and Bartels, 1996; Hundertmark and Hinch, 2008). A number of studies have demonstrated that dehydrin proteins play an important role in drought tolerance by preventing membrane denaturation and maintaining the integrity of the CW (Lopez et al., 2003; Collett et al., 2004; Vicré et al., 2004; Samarah et al., 2006; Hu et al., 2010). Dehydrins are known to undergo phosphorylation both *in vivo* and *in vitro* (Heyen et al., 2002; Jiang and Wang, 2004; Alsheikh et al., 2005; Brini et al., 2006; Röhrig et al., 2006). However, we are aware

that Pro-Q Diamond staining for phosphoproteins includes a risk of false positive identifications. Therefore, a mass spectrometral approach was employed to verify phosphorylation and to identify the phosphorylation site of this dehydrin. Unfortunately, we could not identify the phosphorylation site of dehydrin successfully by MS because the protein amount available was insufficient for the quantification. Thus, the confirmation of the phosphorylation of dehydrin awaits further work in the future.

Dehydrins were found to be localized in various subcellular sites including plasma membrane, cytoplasm and nucleus (Danyluk et al., 1998; Wisniewski et al., 1999; Carjuzaa et al., 2008). Recently, Layton et al. (2010) observed that dehydrin mainly accumulated near the CW of dried tissues in the desiccation-tolerant fern *Polypodium polypodioides*. The author supposed that the ability to avoid CW damage in some desiccation-tolerant species may be partially attributed to CW localization of dehydrins enabling reversible great CW deformation. Dehydrins are extremely hydrophilic proteins (Close et al., 1989), which can attract, sequester and localize water and may behave as a lubricant between either, the plant CW and cell membrane or between individual CW layers. It has been reported that dehydrins are highly specialized proteins that lack a fixed three-dimensional structure and have evolved to maintain their disordered character under conditions such as water deficit, in which unfolded states of several globular proteins would tend to collapse (Mouillon et al., 2008). However, the effect of phosphorylation on dehydrin structure is small and does not significantly enhance the response to osmotic stress induced by glycecol and PEG 4000 *in vitro* (Mouillon et al., 2008). In spite of this, the studies *in vitro* may not reflect the response of dehydrin structure to phosphorylation *in vivo*, since dehydrins may interact with other proteins *in vivo*. In addition the site of osmotic stress induced by glycerol and PEG 4000 is different from PEG 6000 because of the differences in molecular weight; the former solutes mainly induce OS in the cytoplasm while the latter mainly in the apoplast (Yang et al., 2010). Thus, it appears that the increased dehydrin formation could play an important role in the protection of CW against breakage and in the maintenance of the mechanical CW integrity. Our previous study (Yang et al., 2010) suggested that CW porosity was reduced by PEG-induced OS and quickly recovered after the removal of OS in root tips of common bean, which was concluded on the basis of the penetration of ions with different hydrated ionic radius ($\text{Al}^{3+} > \text{La}^{3+} > \text{Sr}^{2+} > \text{Rb}^{+}$) into the apoplast. Therefore, dehydrins may prevent CW from PEG-caused mechanical fracture, and consequently maintain the elastic extension (reversible stretching) properties of the CW and thus allow quick reversion of CW extension after removal of osmotic stress.

Importantly, the above hypothesis also provides the opportunity to further clarify the exact cellular localization of dehydrins in root tips of common bean prior to the analysis of phosphorylation sites of dehydrin, in order to better understand the potential roles of dehydrin in the reduction and rapid recovery of CW porosity during OS.

In conclusion, the large-scale proteomic analysis revealed the importance of carbohydrate and amino acid metabolism involved in the response of root tips to osmotic stress. The phosphoproteomics provided novel insights into the potential role of dehydrin as a CW structure moderator, which may participate in alteration of CW porosity by maintaining the integrity and reversible extension properties of the CW during OS. Future research is necessary to further clarify the cellular localization of dehydrin and its possible role in CW modification.

CHAPTER 4**Physiological and molecular analysis of the interaction between
aluminum toxicity and drought stress in common bean (*Phaseolus
vulgaris* L.)**

(To be submitted)

Abstract

Aluminium (Al) toxicity and drought are two major factors limiting common bean (*Phaseolus vulgaris* L.) production in the tropics. In the present study short-term effects of combined Al toxicity and drought stress on root growth in an acid, Al-toxic soil were studied with special emphasis on Al/drought interaction in the root apex at the physiological and molecular level. The root elongation rate of Al-sensitive bean genotype VAX 1 was significantly inhibited by both increased Al supply and reduced soil moisture. Drought reduced Al toxicity as indicated by the reduction of Al-induced callose formation and lower expression level of a *MATE* gene in root tips. However, in contrast to PEG-induced reduction of Al injury in hydroponics, combined Al and drought stress in soil resulted in a more severe inhibition of root elongation than either stress alone. This finding is consistent with Al-enhanced drought-induced up-regulation of *ACCO* gene expression, Al-reduced drought-induced enhancement of ABA concentration and the expression of genes and transcription factors involved in ABA biosynthesis and gene regulation, and Al-stimulated synthesis of zeatin riboside in the root tips by Al. Six genes, each with possible role in the regulation of cell-wall properties and response to osmotic stress were (with only one exception) comparably affected by osmotic stress (PEG) and by drought stress in soil. Al remarkably reduced or further increased the expression of drought-affected genes in agreement with reduced drought resistance in presence of Al. Taken together, these results provide circumstantial evidence that drought alleviates Al toxicity, but Al renders the root apex more sensitive to drought particularly by impacting the gene regulatory network involved in ABA signal transduction and ABA signal cross-talk with other phytohormones that are necessary for maintaining root growth under drought.

Key words: abscisic acid, *ACCO*, aluminum, common bean, cytokinin, drought, ethylene, *MATE*, *NCED*, polyethylene glycol, root elongation, zeatin riboside

Introduction

Common bean (*Phaseolus vulgaris* L.) is the major food legume for human nutrition in the world, and a major source of calories and protein particularly in many developing Latin American and African countries (Graham, 1978; Rao, 2001). Bean production in the tropics is severely limited by two major abiotic stresses, drought and Al toxicity (Goldman et al., 1989; Ishitani et al., 2004). Generally, common bean has been regarded as an Al and drought-sensitive crop (Rao, 2001; Beebe et al., 2008).

Al resistance in common bean is related to lower Al accumulation in the root tips (Rangel et al., 2007). Under short-term Al exposure, Al accumulates primarily in the root apoplast (Wang et al., 2004; Rangel et al., 2009) where Al^{3+} strongly binds to the negatively charged binding sites (Blamey et al., 1990; Horst et al., 2010) provided by unmethylated pectin in the cell wall (CW) (Schmohl et al., 2000; Eticha et al., 2005a). Thus, a lower CW negativity reducing Al accumulation (Horst, 1995) and the detoxification of Al in the apoplast through root exudates play key roles in Al resistance. Excluding Al from the root apex by releasing organic acid anions such as citrate, malate and oxalate is the most studied mechanism of Al resistance (Ryan et al., 2001; Ma et al., 2001; Kochian et al., 2004; Ma, 2007; Ryan et al., 2007; Ryan and Delhaize, 2010). In common bean, Rangel et al. (2010) found that Al-activated exudation of citrate from root tips plays a major role in Al resistance. Further studies by Eticha et al. (2010) showed that the Al-induced expression of a *MATE* (multidrug and toxin extrusion family protein) gene in root apices is a prerequisite for citrate exudation and Al resistance in common bean, and a most sensitive indicator of Al injury. A role of *MATE* organic acid anion permeases for Al resistance has been reported in several plant species, such as sorghum (Magalhaes et al., 2007), barley (Furukawa et al., 2007), wheat (Ryan et al., 2009) and *Arabidopsis* (Liu et al., 2009). Whereas the expression of the *MATE* gene did not differ between two common bean genotypes, Quimbaya (Al-resistant) and VAX 1 (Al-sensitive), the genotypic difference in Al-induced inhibition of root elongation was positively correlated with the expression of an *ACCO* (1-aminocyclopropane-1-carboxylic acid oxidase) gene in the root apex (Eticha et al., 2010). Enhanced *ACCO* gene expression may lead to an increase of ethylene production which may contribute to Al-induced inhibition of root elongation as observed in *Lotus japonicus* and *Medicago truncatula* (Sun et al., 2007). Since the expressions of the *MATE* and *ACCO* genes were significantly negatively correlated with Al-induced inhibition of root elongation and positively correlated with the Al contents in the root tips

of common bean (Yang et al., 2011), they can be regarded as sensitive indicators of Al toxicity and Al accumulation in the root tips.

The maintenance of root growth during water deficit facilitates water uptake from the subsoil (Sponchiado et al., 1989; Serraj and Sinclair, 2002). In maize, three possible mechanisms involved in the primary root growth maintenance under water deficit have been proposed i) osmotic adjustment; ii) modification of cell wall extension properties; and iii) the role of abscisic acid (ABA) accumulation (Sharp et al., 2004; Yamaguchi et al., 2010). Using SuperSAGE (serial analysis of gene expression) and quantitative real time polymerase chain reaction (qRT-PCR), our previous studies demonstrated that polyethylene glycol (PEG)-simulated drought stress up or down-regulated some genes involved in osmotic stress such as aquaporin (*AQP*), Δ 1-pyrroline-5-carboxylate synthase (*P5CS*), sucrose synthase (*SUS*), late embryogenesis abundant (*LEA*), KS-type dehydrin (*KS-DHN*) and cytochrome P450 monooxygenase *CYP701A* (*CYP701A*), cell-wall assembling or modifying genes such as xyloglucan endotransglucosylase/hydrolase (*XTH*), glucan endo-1,3-beta-glucosidase (*BEG*), proline-rich protein (*PRP*), hydroxyproline-rich glycoprotein (*HRGP*), lipid transfer protein (*LTP*), and the regulation of ABA-dependent drought stress such as transcription factors *bZIP* and *MYB* in the root tips of common bean (Yang et al., 2011). ABA is produced under water-deficit conditions and plays an important role in the response of plants to drought. The accumulation of ABA in the root tips has been shown to be required for the maintenance of maize primary root elongation at low water potentials (Sharp, 2002; Sharp et al., 2004; Yamaguchi and Sharp, 2010). Using the ABA-deficient mutant *vp5* and a chemical inhibitor of ABA biosynthesis to decrease endogenous ABA levels in seedlings growing at low water potentials, Sharp et al. (2004) reported that reduced ABA accumulation in maize primary roots was associated with more severe inhibition of root elongation. Under drought, ABA accumulated mainly towards the root apex (Saab et al., 1992) indicating that it was required for the maintenance of elongation in the distal elongation zone at low water potentials (Yamaguchi and Sharp, 2010). On the other hand, several studies have clearly shown that ABA can suppress ethylene production, and the maintenance of root elongation under water deficit conditions requires increased ABA levels to prevent excess ethylene production (Sharp et al., 2000; Spollen et al., 2000; Sharp, 2002; LeNoble et al., 2004), which can mediate the cytokinin (CK)-induced inhibition of root elongation (Bertell and Eliasson, 1992; Cary et al., 1995; Růžička et al., 2009).

It has been reported that cell elongation was maintained at low water potentials in the

apical 0-3 mm and 0-4 mm of the root in maize and soybean, respectively (Sharp et al., 2004; Yamaguchi et al., 2010). However, the root apex is the most Al-sensitive root zone (Horst et al., 1992; Delhaize and Ryan, 1995). In common bean, Rangel et al. (2007) found that the transition zone (1-2 mm) and the elongation zone are targets of Al injury. Excess Al will result in a rapid inhibition of root elongation and enhanced callose synthesis in the root tips, both are sensitive indicators of Al injury in roots (Horst et al., 1992; Delhaize and Ryan, 1995; Staß and Horst, 2009). Therefore, in dried acid soil, the Al-impeded root growth may strongly restrict the exploitation of water from the subsoil and thus the ability of the roots to withstand drought stress (Goldman et al., 1989). However, using different bean species, Butare et al. (2011) found that Al partially ameliorated the negative effects of water stress in *Phaseolus coccineus* genotypes, strongly in contrast to *Phaseolus acutifolius* and the Mesoamerican common bean genotypes in which combined stress led to a more severe inhibition of root development. Using PEG 6000 to simulate drought stress (Carpita et al., 1979; Jia et al., 2001; Fan and Neumann, 2004; Yang et al., 2010), we found that PEG 6000-induced osmotic stress can reduce Al-induced inhibition of root elongation by inhibiting Al accumulation in the root tip of common bean genotype VAX 1 (Yang et al., 2010). Also, the positive PEG effect on Al injury was confirmed by the expression of the *MATE* and *ACCO* genes, as sensitive indicators of Al toxicity (Yang et al., 2011). The PEG-suppressed Al accumulation in the root tips was suggested to be due to the osmotic stress-induced reduction of CW porosity, involving the regulation of the expression of the genes *XTH*, *BEG* and *HRGP* (Yang et al., 2011).

Although PEG 6000 can induce water deficit due to dehydration of the root apoplast (Yang et al., 2010), PEG treated hydroponic system and dried soil system are two completely different systems. Thus, the interaction between PEG-induced water deficit and Al toxicity in common bean may not reflect soil conditions. Therefore, the main objective of the present study was to determine the short-term effects of combined Al toxicity and drought stress on root growth in an acid, Al-toxic soil with special emphasis on Al/drought interaction in the root apex of the Al-sensitive common bean genotype VAX 1 at the physiological and molecular level.

Materials and Methods

Soil properties and preparation

The acid soil was obtained from Matazul farm (4°9'N 72°39'W) in the Llanos region of Colombia. Soil chemical characteristics are shown in Tab. 1. The soil pH was measured in 0.01 M CaCl₂ solution (pH_CaCl₂) or distilled water (pH_H₂O) with 1:3 soil:extract ratio (w/v). For the determination of soil exchangeable acidity, H⁺ and Al³⁺ were determined by NaOH titration using 1% phenolphthalein and 0.1% methyl orange after extracting with 1 M KCl. For the measurement of the effective cation exchange capacity (ECEC), 2 g air-dried soil was weighed in a 30-mL centrifuge tube. 10 mL deionized water was added and the suspension shaken for 1 h. After centrifugation at 5,000 g the supernatant was discarded. The pellet was washed first with 20 mL 70% ethanol and then with 20 mL 10% ethylene glycol (C₂H₆O₂). After discarding the supernatant 10 mL 0.2 M BaCl₂/0.2 M NH₄Cl solution was added, shaken for a further 2 h, centrifuged and in the supernatant Ca, Mg, K, Na and Al were determined by inductively coupled plasma mass spectroscopy (ICP-MS) (7500cx, Agilent Technology, Santa Clara, California, USA). The ECEC was calculated by the formula: $ECEC = Ca^{2+} + Mg^{2+} + Na^{+} + K^{+} + Al^{3+}$ representing exchangeable cations in centimoles of cation charge per kilogram soil (cmol_c kg⁻¹ soil). The Al saturation (%) of the soil was calculated as the ratio of exchangeable Al³⁺/ECEC × 100. The soil water retention was determined and the water retention curve is shown in Supplemental Fig. S2. The soil water potential at different soil moisture used for the drought treatment in this study is shown in Supplemental Fig. S2.

For the soil treatment, first the soil was limed by adding 1.1 g Ca(OH)₂ per kg soil, well mixed and incubated at 25 °C for one week. Then different levels of Al (AlCl₃·6H₂O) (0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0 g kg⁻¹ soil) were added to the limed soils, well mixed and incubated for two weeks. Finally the soil pH_H₂O was 6.5, 5.5, 5.0, 4.7, 4.3, 4.1 and 3.9, respectively, and the corresponding Al concentrations in the water extract were 0.4, 0.7, 1.0, 4.3, 40, 173 and 426 μM (see supplemental Fig. S1). The treated soil was air-dried and stored for future use.

Table 1 Chemical characteristics of an Oxisol collected from Matazul farm in the Llanos region of Colombia

Soil chemical characteristics	Oxisol
pH_CaCl ₂	4.05
pH_H ₂ O	4.89
Exchangeable acidity (cmol _c /kg soil)	1.57
Exchangeable H ⁺ (cmol _c /kg soil)	0.33
Exchangeable Al (cmol _c /kg soil)	1.23
Total Al content (mg/kg soil)	111.0
ECEC (cmol _c /kg soil)	1.49
Al Saturation (%)	89.1

Plant materials and growing conditions

Seeds of common bean (*Phaseolus vulgaris* L.) genotype VAX 1 (Al-sensitive) were germinated for two or three days on filter paper sandwiched between sponges. For the soil experiments uniform seedlings were transferred into the soil with different levels of Al application and/or soil moisture in falcon vials (one plant per vial), covered with Al foil and kept in an upright position for 24 h. For the hydroponic experiments uniform seedlings were transferred to a continuously aerated simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ (Rangel et al., 2007). The pH of the nutrient solution was gradually lowered to 4.5 within two days. Then the plants were transferred into a simplified nutrient solution (see above, pH 4.5) containing AlCl₃ (0, 25 μM Al) and PEG 6000 (0, 150 g L⁻¹) (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) for 24 h. The osmotic potential (OP) of 150 g L⁻¹ PEG 6000 was -0.60 MPa, measured with a cryoscopic osmometer (Osmomat 030, Gonotec GmbH, Berlin, Germany). Plants were cultured in a growth chamber under controlled environmental conditions of a 16/8 h light/dark cycle, 27/25 °C day/night temperature, 70% relative air humidity, and a photon flux density of 230 μmol m⁻² s⁻¹ of photosynthetically active radiation at plant height. One-cm root tips were harvested for Al analysis or immediately frozen in liquid nitrogen in Eppendorf vials for callose and phytohormone determination and RNA isolation.

Measurement of root elongation rate

Before transferring the plants into the soil or the nutrient solution, the tap roots were marked one (for soil) or three (for hydroponics) centimeter behind the primary root tip using a fine point permanent marker (Sharpie blue, Stanford) which did not affect root

growth during the experimental period. Root elongation was measured after treating the plants for 24 h using a mm scale.

RNA isolation and quantitative real time-PCR

After treating the plants in the soil with different Al supplies (0, 1.0, 2.0 g kg⁻¹ soil) and soil moisture (-0.05, -0.14, -0.31 MPa SWP) for 24 h, the roots were rinsed with distilled water, and loosely adhering soil particles were removed with a brush. Primary root tips (1 cm long) from each plant were harvested and shock-frozen in liquid nitrogen. Nine root tips were bulked and ground to powder in liquid nitrogen. Total RNA was isolated using the NucleoSpin RNA plant kit (MACHEREY-NAGEL GmbH and Co., KG, Düren, Germany) following the manufacturer's protocol. After isolating the RNA from the root tips first-strand cDNA was synthesized using RevertAid H-Minus first strand cDNA synthesis kit (Fermentas, www.fermentas.com) following the manufacturer's protocol. Quantitative Real Time PCR (qRT-PCR) was performed using the CFX96TM Real Time System plus C1000TM Thermal Cycler (www.bio-rad.com). The SYBR Green detection system was used with self-prepared SYBR Green master mix. The qRT-PCR reaction mix composed of 1 × hot-start PCR buffer (DNA Cloning Service, Germany), 3.6 mM MgCl₂ (DNA Cloning Service, Germany), 200 μM each dNTP (dATP, dTTP dCTP dGTP) (Fermentas), 0.1 × SYBR Green-I (Invitrogen), 0.75 U μL⁻¹ DCSHot DNA Polymerase (DNA Cloning Service, Germany), 252 nM each forward and reverse primer (Biolegio), 2 ng μL⁻¹ cDNA template and ultra-pure DNase/RNase-free distilled water (Invitrogen) in a final volume of 25 μL. The qRT-PCR cycling stages consist of initial denaturation at 95 °C (10 min), followed by 45 cycles of 95 °C (15 s), 60 °C (30 s), 72 °C (30 s), and a final melting curve stage of 95 °C (15 s), 60 °C (15 s) and 95 °C (15 s). Samples for qRT-PCR were run in three biological replicates and two technical replicates. Relative gene expression was calculated using the comparative ΔΔCT method according to Livak and Schmittgen (2001). For the normalization of gene expression, *β-tubulin* was used as an internal standard according to Eticha et al. (2010), and the control (-0.05 MPa SWP in the absence of Al application) plants of bean genotype VAX 1 were used as reference sample.

Candidate gene selection and primer design for qRT-PCR

Candidate genes were selected either from our previous SuperSAGE library (Yang et al., 2011) or from a public database. The ESTs obtained from the *P. vulgaris* were aligned; otherwise the EST sequences from other legumes were gathered for sequence alignment.

The well conserved regions were used for primer design. Primers were designed using Primer3 software (Rozen and Skaletsky, 2000). The primers of *β-tubulin*, *MATE* and *ACCO* genes were obtained from Eticha et al. (2010). The specifications of the primers of the genes studied are given in Supplemental Table S1. The PCR efficiencies of the primer pairs were in the range of 90 – 110% as determined by dilution series of the cDNA template. Primer pairs with PCR efficiencies deviating from this range were discarded and new primers of the genes were designed to get more reliable quantification.

Determination of Al

For the determination of Al in roots, 1-cm root tips were digested in 500 μ L ultra-pure HNO₃ (65%, v/v) by overnight shaking on a rotary shaker. The digestion was completed by heating the samples in a water bath at 80 °C for 20 min. Then 1.5 mL ultra-pure deionised water was added after cooling the samples in an ice-water bath. Aluminium was measured with a Unicam 939 QZ graphite furnace atomic absorption spectrophotometer (GFAAS; Analytical Technologies Inc., Cambridge, UK) at a wavelength of 308.2 nm after appropriate dilution, and an injection volume of 20 μ L.

Determination of callose

Root tips of 1 cm length were excised from primary roots of three plants, collected in Eppendorf reaction vials, and instantly frozen in liquid N₂. The root tips were homogenized in 500 mL of 1 M NaOH with a mixer mill (MM 200; Retsch GmbH & Co. KG, Haan, Germany) at a speed of 20 cycles s⁻¹ for 2 min. After homogenization, another 500 mL of 1 M NaOH was added, and callose was solubilized by heating in a water bath at 80 °C for 20 min. Callose was measured according to Kauss (1989), after addition of aniline blue reagent using a microplate fluorescence reader (FLx 800, Bio-Tek Instruments, Winooski, VT, USA) at excitation and emission wavelengths of 400 and 485 nm, respectively. Pachyman (1, 3- β -D-glucan) was used as a calibration standard, and thus, root callose content was expressed as pachyman equivalents (PE) per cm root tip.

Analysis of phytohormones

Different forms of CKs, IAA, ABA, JA and SA were extracted and purified according to Albacete et al. (2008) with some modifications. Primary root tips (1 cm long) were excised from common bean genotype VAX 1 and immediately frozen in liquid N₂. The root tips were ground to powder in liquid nitrogen. Afterwards, 1 mL of 80% (v/v) methanol was

added into each sample and vortexed. Then 4 μL of internal standard mix (5 $\mu\text{g mL}^{-1}$) composed of deuterium-labelled hormones ($[\text{}^2\text{H}_5]\text{Z}$, $[\text{}^2\text{H}_5]\text{ZR}$, $[\text{}^2\text{H}_5]\text{ZOG}$, $[\text{}^2\text{H}_5]\text{ZROG}$, $[\text{}^2\text{H}_6]\text{iP}$, $[\text{}^2\text{H}_5]\text{DHZ}$, $[\text{}^2\text{H}_5]\text{DHZR}$, $[\text{}^2\text{H}_6]\text{ABA}$, $[\text{}^2\text{H}_3]\text{IAA}$, and $[\text{}^2\text{H}_5]\text{JA}$, Olchemin Ltd, Olomouc, Czech Republic) was added, well mixed and incubated for 30 min at 4 $^\circ\text{C}$. Afterwards, the samples were centrifuged at 20,000 g and 4 $^\circ\text{C}$ for 15 min. The supernatant was carefully pipetted into a syringe and passed through pre-equilibrated Chromafix C18 columns (Macherey-Nagel, Düren, Germany) with 80% (v/v) methanol. Samples were collected in 5 mL tubes on ice and 1 mL 80% (v/v) methanol was added and vortexed thoroughly. After centrifuging at 20,000 g and 4 $^\circ\text{C}$ for 15 min the filtration step was repeated. The collected samples were concentrated to dryness using a Thermo ISS110 centrifugal vacuum evaporator (Thermo Savant, Holbrook, NY, USA). The concentrated residue from each sample was re-dissolved in 500 μL 20% (v/v) methanol, sonicated for 8 min, filtrated through 0.22 μm syringe filters (Chromafil PES-20/25, Macherey-Nagel, Düren, Germany) and collected in 1.5 mL Eppendorf vials. The samples were immediately frozen for phytohormone measurement.

Analyses were carried out on a UPCL-MS/MS system consisting of a Thermo ACCELA UPLC (Thermo Scientific, Waltham, Massachusetts, USA) coupled to a thermostated HTPAL autosampler (CTC Analytics, Zwingen, Switzerland), and connected to a Thermo TSQ Quantum Acces Max Mass Spectrometer (Thermo Scientific, Waltham, Massachusetts, USA) with a heated electrospray ionization (HESI) interface. Standards with known concentrations of each hormone (0.5, 0.1, 0.05, 0.01, 0.005 $\mu\text{g mL}^{-1}$) and the internal standards (0.01 $\mu\text{g mL}^{-1}$) were prepared in a 80% (v/v) methanol solution, and filtrated through 0.22 μm syringe filters (Chromafil PES-20/25, Macherey-Nagel, Düren, Germany). Ten μL of each standard or sample were injected onto a Thermo Hypersil Gold column (1.9 μm , 50 x 2.1 mm, Thermo Scientific, Waltham, Massachusetts, USA) eluted at a flow rate of 250 $\mu\text{L min}^{-1}$. Mobile phase A consisting of water/methanol/acetic acid (89.5/10/0.5, v/v/v) and mobile phase B consisting of methanol/acetic acid (99.5/0.5, v/v) were used for chromatographic separation. The elution consisted in 2 min of 95% A and a linear gradient from 5 to 100% of B in 8 min. 100% B was maintained 6 min and afterwards the column was equilibrated with the starting composition (95% A) for 8 min before each analytical run. The mass spectrometer was operated in the positive mode for all the hormones analyzed, except JA and SA that were measured in the negative mode. Capillary spray voltage was set to 4,000 V, the nebulizer gas (He) pressure to 40 psi with a flow rate of 8 L s^{-1} at a temperature of 250 $^\circ\text{C}$, and the scan cycle time was 0.5 s from 100

to 600 m/z. The chromatogram of each hormone from both standards and samples was extracted, and the peak area quantified using the Thermo XCalibur software version 2.1.0.

Statistical analysis

A completely randomized design was used with four to twelve replicates in each experiment. Statistical analysis (ANOVA) was carried out using SAS 9.2. Means were compared using t or Tukey test depending on the number of treatments being compared. *, **, *** denote significant differences at $P < 0.05$, 0.01, 0.001, respectively.

Results

Application of AlCl_3 (0 - 3.0 g Al kg^{-1} soil) to the acid soil limed to pH 6.5 reduced the soil pH (H_2O) to 3.9 after incubation for two weeks, and the reduction of soil pH was correlated with an increase of Al concentration in the water extract (Supplemental Fig. S1). The root elongation rate of the common bean genotype VAX 1 was increasingly inhibited by the application of increasing Al rates (Fig. 1A). The supply of 1.0 and 2.0 g Al kg^{-1} soil reduced the root elongation rate by 29% and 52%, respectively, compared to the control (no Al). Decreasing soil water potential (SWP) from -0.05 to -0.87 MPa also drastically reduced root elongation. Medium to severe drought stress at -0.14 MPa and -0.31 MPa SWP inhibited root elongation rate by 45% and 68%, respectively, compared to the well-watered control (-0.05 MPa SWP).

Since a meaningful determination of Al contents of root tips in soil-grown plants is not possible, we evaluated the suitability of the callose content of root tips as indicator of Al injury in soils. In hydroponics, a significant negative correlation ($P < 0.001$) between Al contents and root elongation was observed (Fig. 2A). Aluminum induced callose formation in the root tips. The relationship between Al and callose contents could be described by a highly significant positive linear regression (Fig. 2B). Thus the root-tip callose content can be used as a sensitive indicator of Al-induced inhibition of root elongation rate in hydroponics (Fig. 2C). Similarly, in the soil-culture experiment addition of Al enhanced the root-tip callose contents (Fig. 2D). Thus callose content proved to be a sensitive indicator of Al injury (inhibition of root elongation) in the soil culture experiment also (Fig. 2E).

In order to verify whether Al-induced callose formation is also a reliable indicator of Al stress under combined Al and drought stress, we first conducted a hydroponic experiment using PEG 6000, which cannot penetrate into the root apoplast because of its high molecular weight (Carpita et al., 1979), to simulate drought stress. PEG at -0.60 MPa osmotic potential (OP) significantly reduced root elongation (Fig. 3A) but did not stimulate callose formation (Fig. 3C). 25 μM Al strongly inhibited root elongation (Fig. 3A) and increased root-tip Al (Fig. 3B) and callose contents (Fig. 3C). Combined PEG/Al stress alleviated the Al-induced inhibition of root elongation (Fig. 3A) by reducing the Al accumulation in the root tips (Fig. 3B). The PEG-caused alleviation of the Al stress is also clearly shown by reduced callose formation (Fig. 3C) suggesting a high sensitivity and specificity of callose formation for Al toxicity.

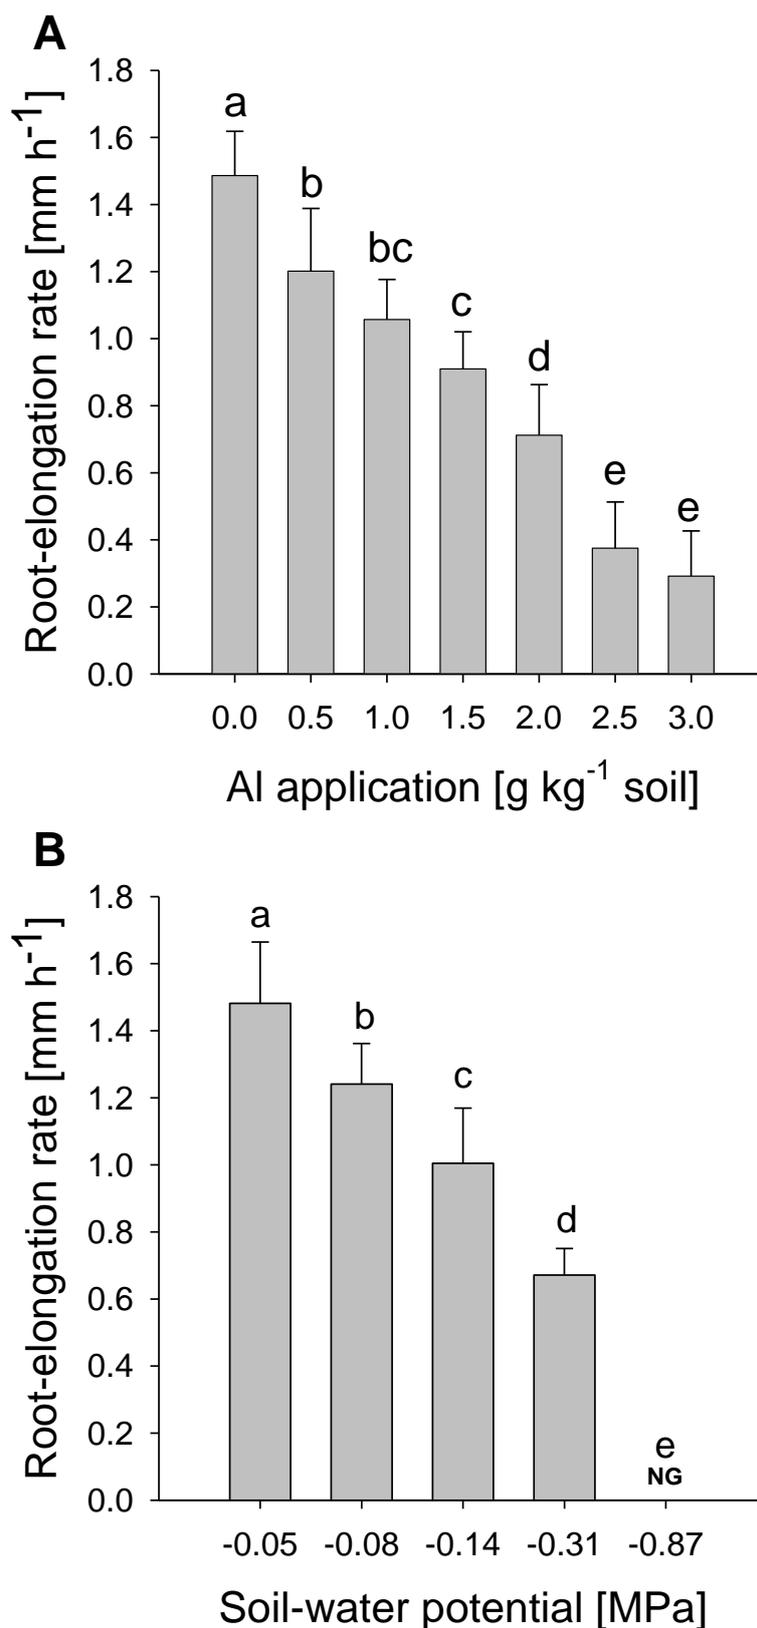

Figure 1 Root-elongation rate at different levels of Al supply under well-watered conditions (A) and at different levels of soil-water potentials in the absence of Al application (pH 6.5) (B). Two-day-old seedlings were grown in the soil for 24 h. Bars represent means \pm SD, $n = 12$. Means with different letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatments. NG = no growth.

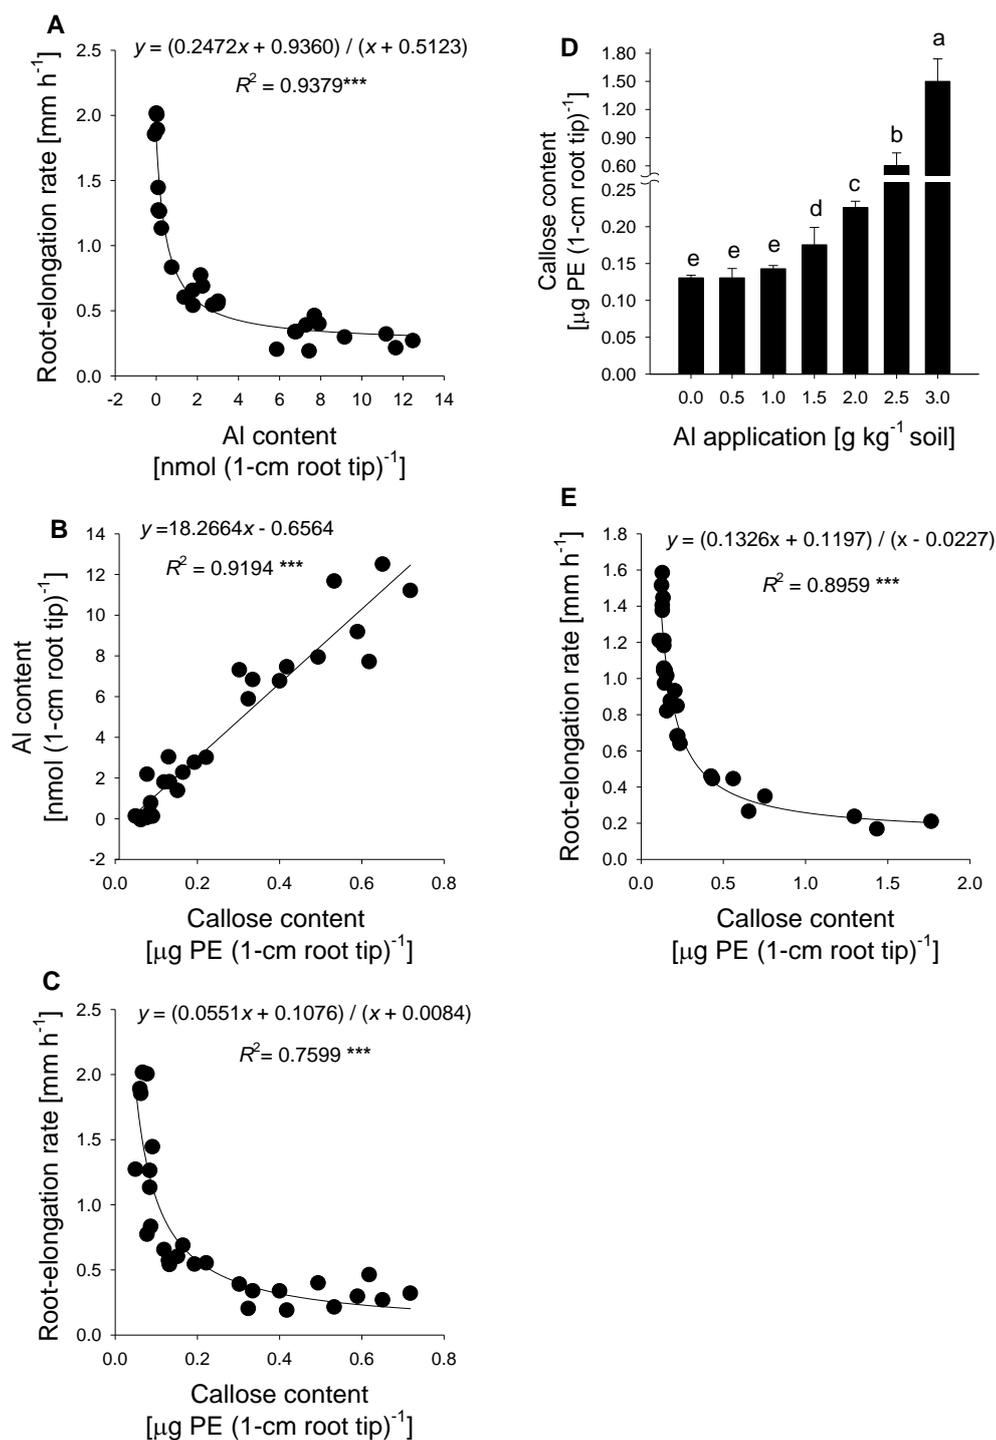

Figure 2 Correlations between root-elongation rate, Al and callose contents in the 1-cm root tips of common bean genotype VAX 1 in nutrient solution (A, B, C) or soil (E), and the effect of soil Al treatment on callose contents in the root tips (D). A, B, C: Plants were pre-cultured in simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation; then the plants were exposed to 25 μM Al in the simplified nutrient solution for 24 h, pH 4.5. D, E: Two-day-old seedlings were grown in well watered (-0.05 MPa SWP) soil with different levels of Al supply for 24 h. In D, bars represent means \pm SD, $n = 4$, and means with different letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatments. For the regression analysis, *** denote significant at $P < 0.001$.

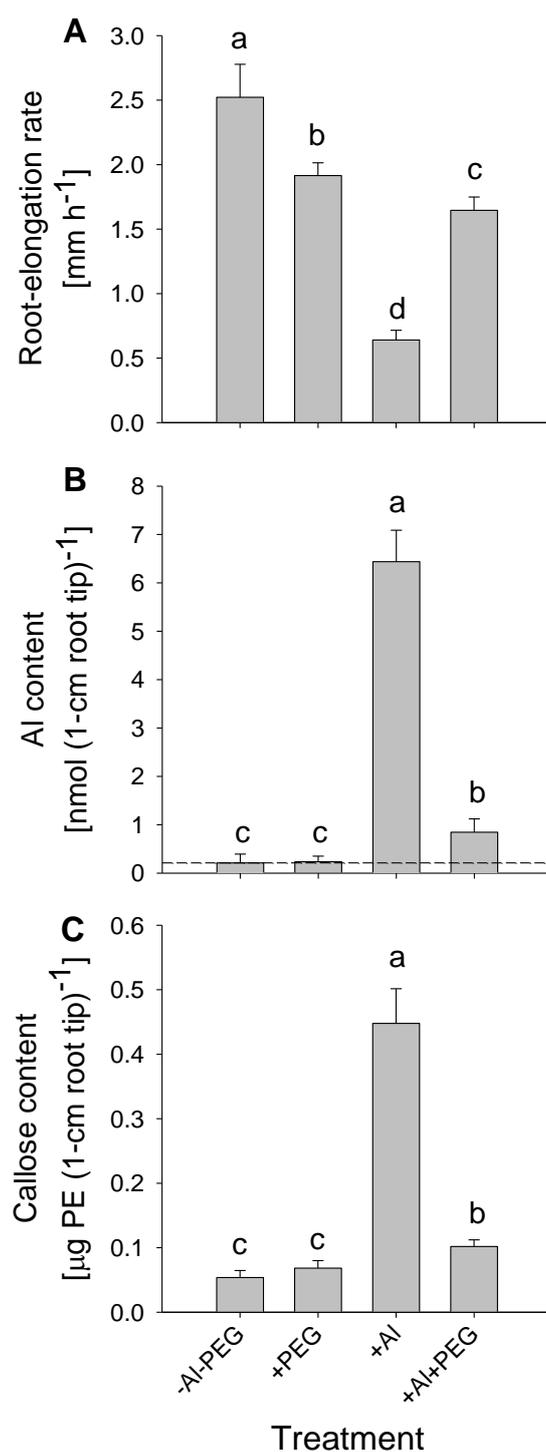

Figure 3 Root-elongation rate (A), Al (B) and callose (C) contents in 1-cm root tips of the common bean genotype VAX 1 under osmotic (0, -0.60 MPa OP) and Al stress (0, 25 μM Al). Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl_2 , 1 mM KCl, and 8 μM H_3BO_3 for 48 h for acclimation and pH adaptation, then treated without or with 25 μM Al in the absence or presence of PEG (150 g L⁻¹ PEG 6000) in the simplified nutrient solution for 24 h, pH 4.5. The background value (dashed line) in (B) presents the mean Al content of the root tips without Al treatment. Bars represent means \pm SD, $n = 12$ for (A) and $n = 4$ for (B, C). Means with different letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatments.

Unlike the hydroponic experiment with PEG (see Fig. 3), in the soil experiment, combined drought (-0.31 MPa SWP) and Al stresses enhanced the inhibition of root elongation beyond the effects of the individual stresses (Fig. 4A, B) in spite of reduced Al stress as indicated by the significant reduction of callose formation in the root tips (Fig. 4C).

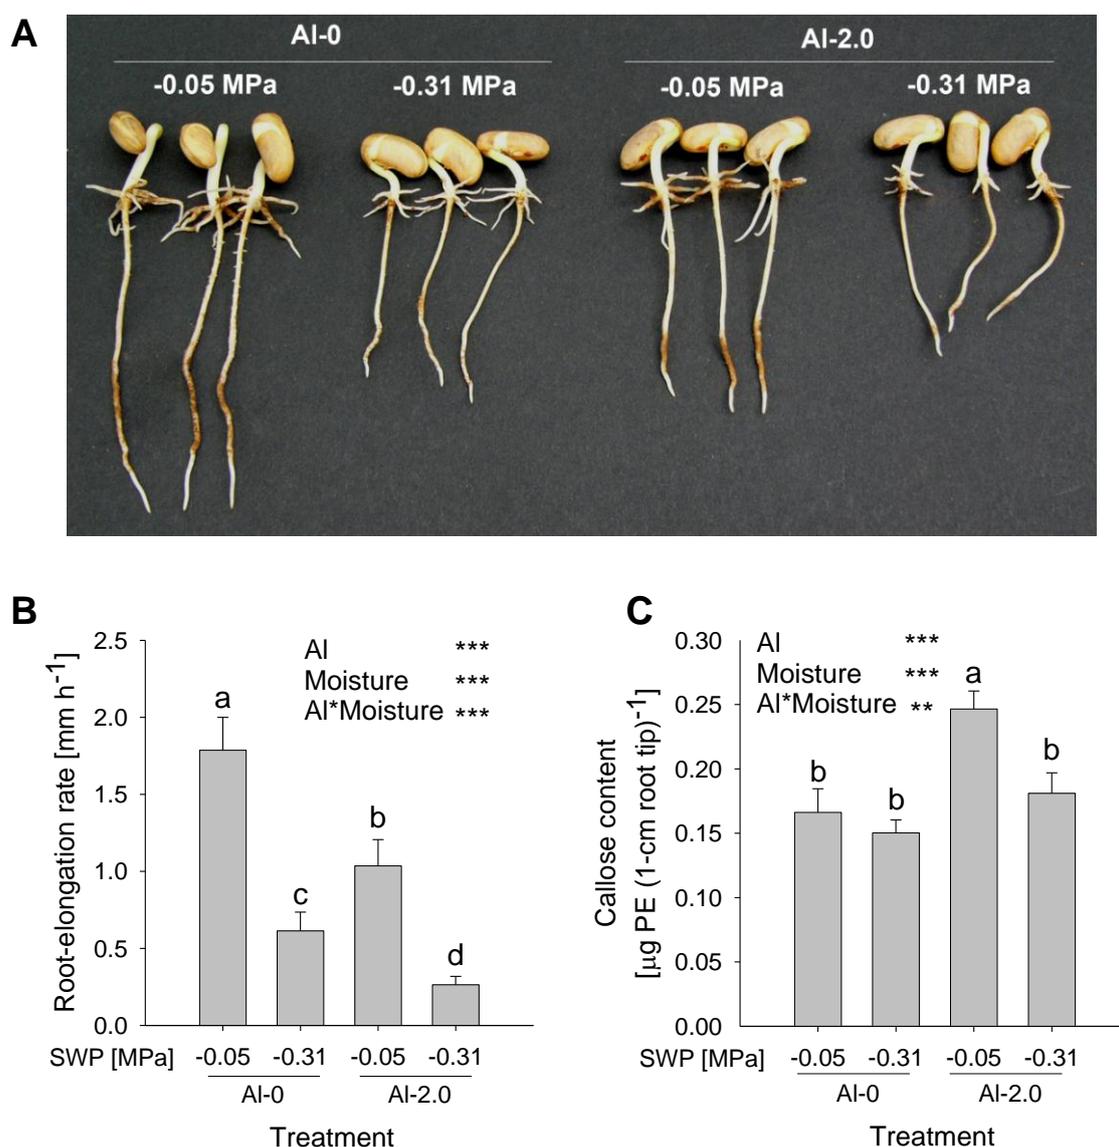

Figure 4 Seedling appearance (A), root-elongation rate (B) and callose contents in the 1-cm root tips (C) of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. Bars represent means \pm SD, $n = 12$ for (B) and $n = 4$ for (C). Means with different letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of treatments. For the ANOVA, **, *** denote significant differences at $P < 0.01$, $P < 0.001$, respectively. SWP, soil-water potential.

To better understand the interaction between Al toxicity and drought in soil, both Al

supply and soil moisture, were varied in three rates in a factorial combination (0, 1.0 and 2.0 g Al and -0.05, -0.14, and -0.31 MPa SWP). The results confirmed that Al supply could enhance drought-induced inhibition of root elongation at all stress levels (Fig. 5A). Similar to osmotic stress, increasing drought stress reduced Al-induced root-tip callose formation confirming the amelioration of Al toxicity by drought (Fig. 5B). This observation is supported by the expression of a citrate transporter *MATE* gene which sensitively responds to Al treatment. Particularly the high Al supply strongly enhanced the expression of the *MATE* gene (Fig. 6A). High drought stress which only slightly stimulated the *MATE* gene expression, significantly suppressed the Al-induced gene expression confirming reduced Al stress as indicated by reduced callose formation (see above, Figs. 4 and 5). The *ACCO* gene sensitively responded to both Al and drought stresses (Fig. 6B). At all soil moisture levels, Al further enhanced the drought-induced up-regulated *ACCO* gene expression which is in agreement with the enhanced inhibition of root elongation at combined Al and drought stress factors (see above, Figs. 4 and 5).

From an analysis of PEG-induced changes in gene transcription in common bean root tips using SuperSAGE (Yang et al., 2011) we selected twelve genes with possible roles in the regulation of cell-wall properties and response to osmotic stress. In agreement with these results eleven of the selected genes were comparably affected osmotic stress (Yang et al., 2011) and by drought stress in soil (Fig. 7): six genes (*P5CS*, *SUS*, *HRGP*, *KS-DHN*, *PvLEA18* and *LTP*) were strongly up-regulated, one gene (*AQP*) was slightly up-regulated, while four genes (*BEG*, *PRP*, *XTHa* and *XTHb*) were down-regulated. Only the *CYP701A* gene was up-regulated by drought but down-regulated by osmotic (PEG) stress.

Aluminum stress alone (optimum soil moisture, -0.05 MPa SWP) also significantly affected the expression of most genes in the same direction as drought stress (Fig. 7). However, in most cases the effect was small compared to the drought effect. Exceptions were the *BEG*, *PRP* and *XTHa* genes which were affected by Al to the same degree as by decreasing soil moisture. Only the *BEG* gene expression was enhanced by Al but decreased by drought. The Al x soil moisture interaction was significant for all and highly significant for most genes. Al remarkably reduced the drought-enhanced expression of the *SUS*, *KS-DHN*, *PvLEA18* and *LTP* genes but further increased the expression of the *P5CS* and *HPRG* genes (only at the high Al supply).

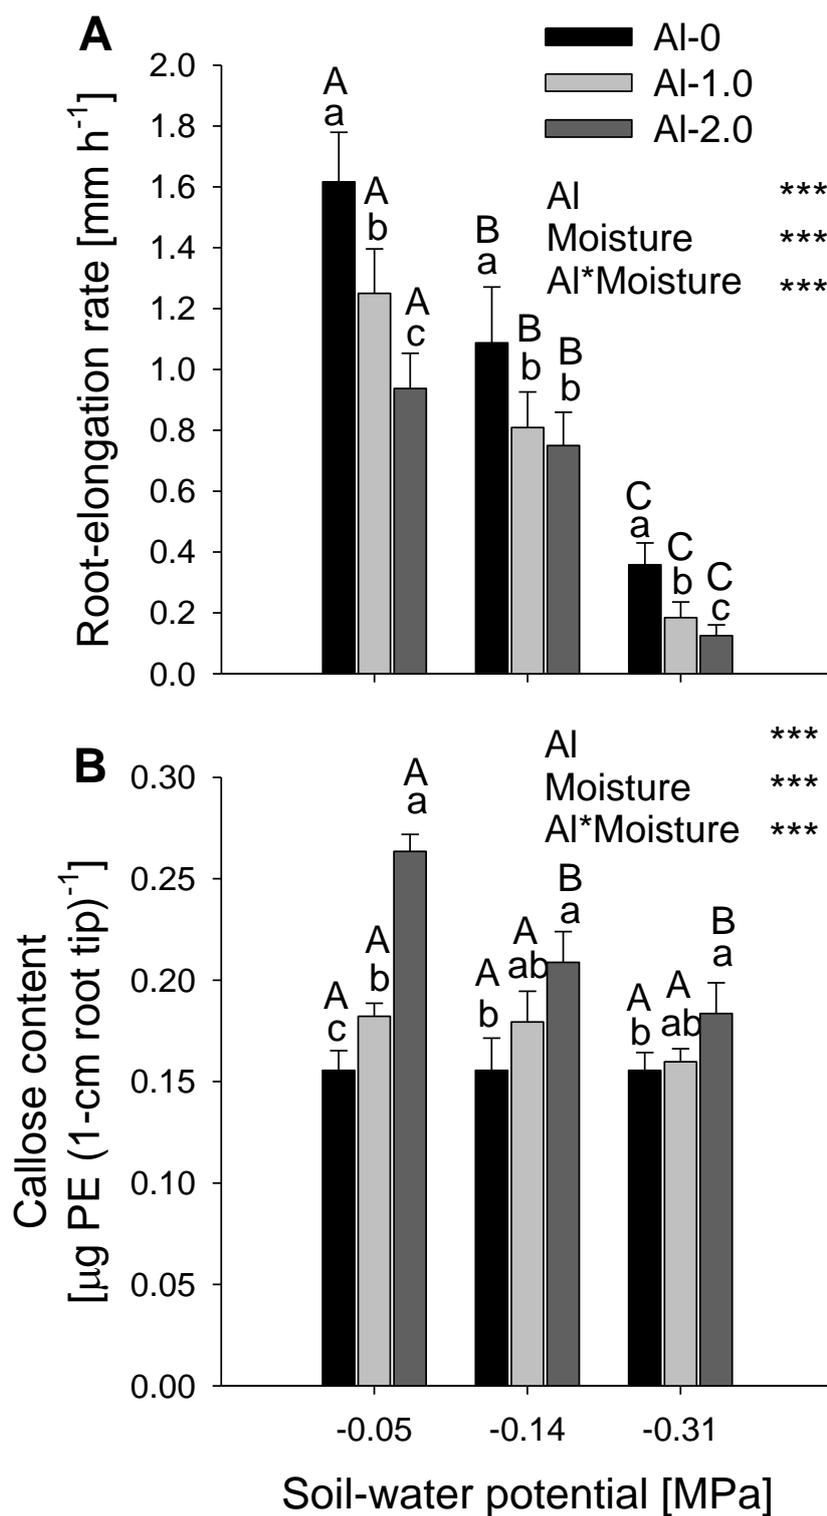

Figure 5 Root-elongation rate (A) and callose contents in the 1-cm root tips (B) of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. Bars represent means \pm SD, $n = 12$ for (A) and $n = 4$ for (B). Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. For the ANOVA, *** denote significant differences at $P < 0.001$.

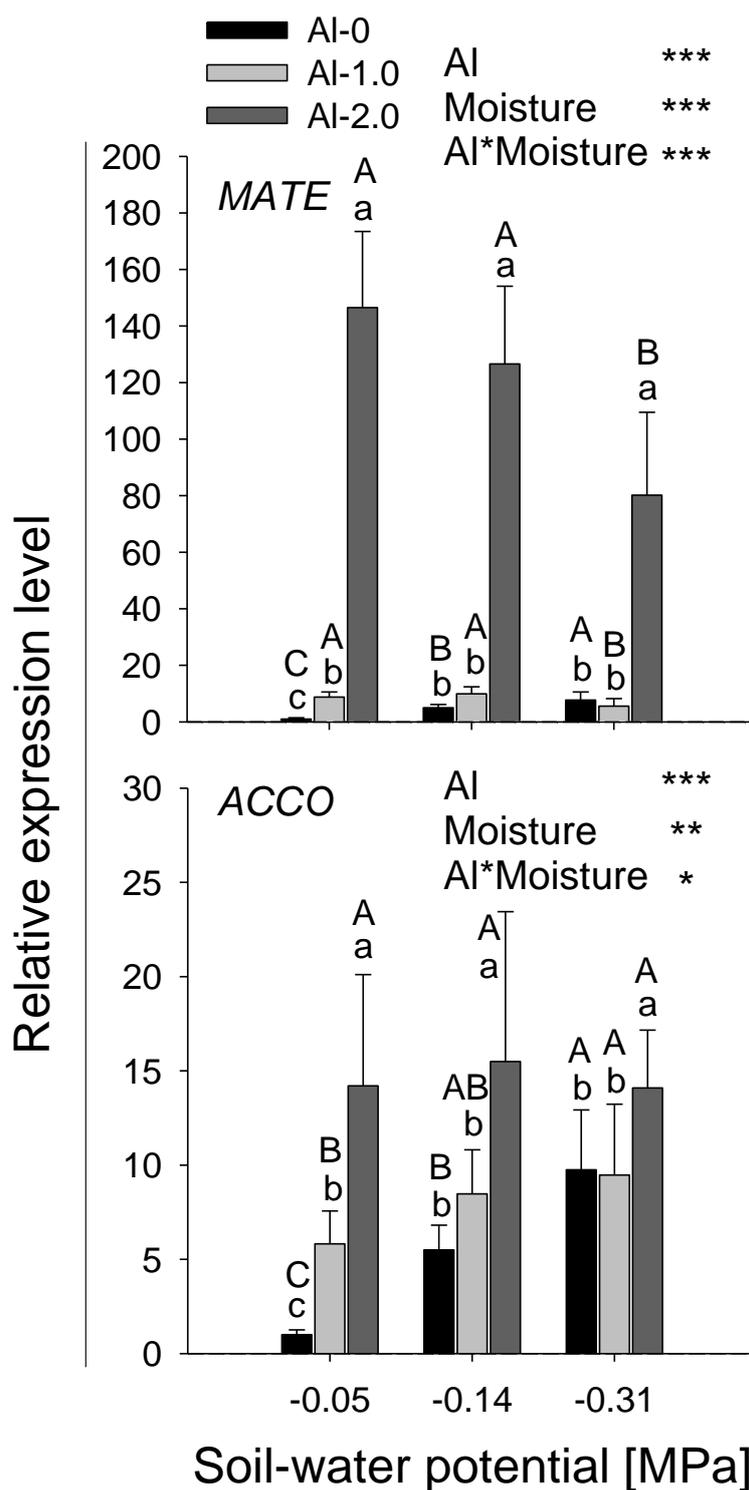

Figure 6 *MATE* and *ACCO* gene expression in the 1-cm root tips of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. qRT-PCR was performed using the β -tubulin gene as internal standard. Bars represent means \pm SD, $n = 3$. Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. For the ANOVA, *, **, *** denote significant differences at $P < 0.05$, $P < 0.01$, $P < 0.001$, respectively.

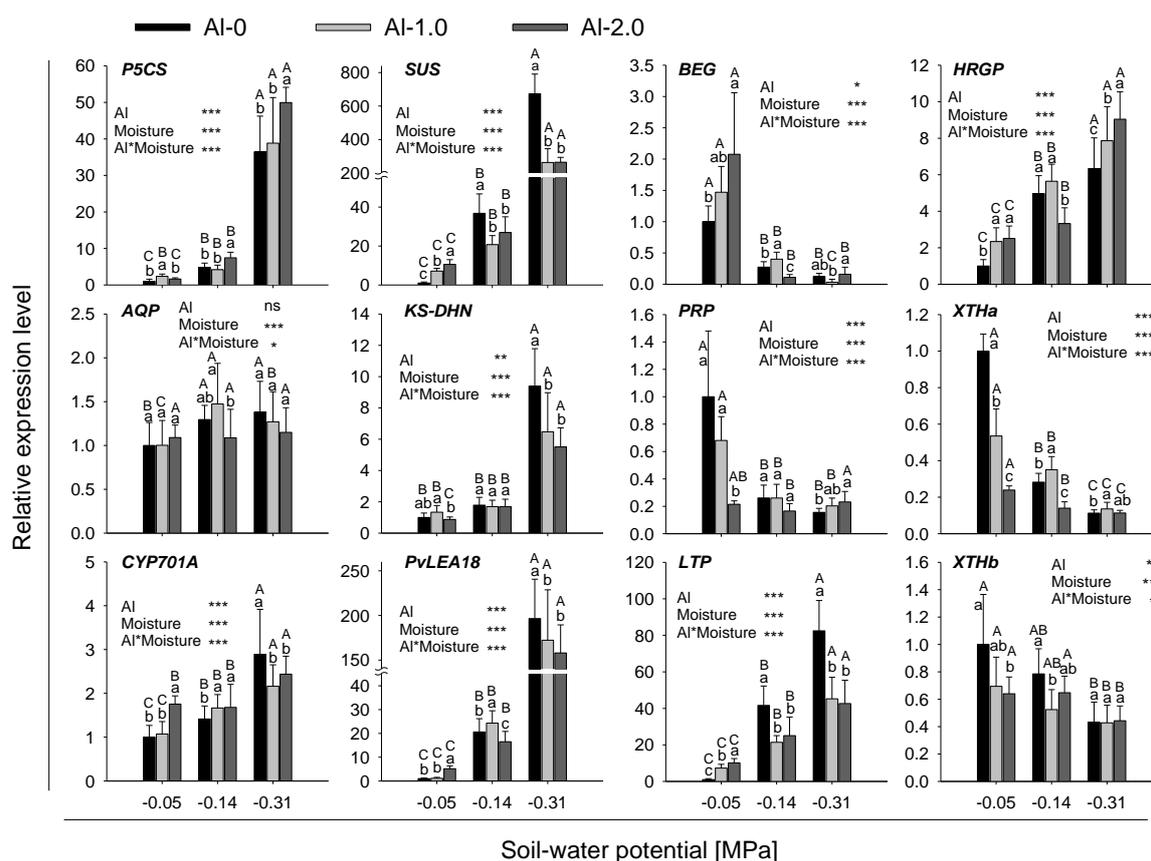

Figure 7 Cell-wall and osmotic stress-associated gene expression in 1-cm root tips of common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. qRT-PCR was performed using the β -tubulin gene as internal standard. Bars represent means \pm SD, $n = 3$. Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. *** denote significant differences at $P < 0.001$. ns = not significant.

Drought stress significantly increased the expression of the genes *NCED* (9-cis-epoxycarotenoid dioxygenase), *ZEP* (zeaxanthin epoxidase), *AAO1* and *AAO2* (abscisic aldehyde oxidase) (Fig. 8B) involved in abscisic acid (ABA) biosynthesis (Fig. 8A). Al markedly affected only the *NCED* gene which was down-regulated at low soil moisture (significant Al \times soil-moisture interaction) reversing the drought-enhanced expression of this gene (Fig. 8B). The expression of the two transcription factors *bZIP* and *MYB* (Fig. 8C) that are involved in the ABA-dependent gene regulation under drought stress (Fig. 8A, Shinozaki and Yamaguchi-Shinozaki, 1997) and selected from our previous analysis of PEG-induced genes expression in common bean root tips using SuperSAGE (Yang et al., 2011), was highly up-regulated by drought (Fig. 8B). In agreement with the *NCED* gene expression, Al stress in addition to drought stress reversed the drought-enhanced gene expression of both transcription factors (highly significant Al \times

soil-moisture interaction).

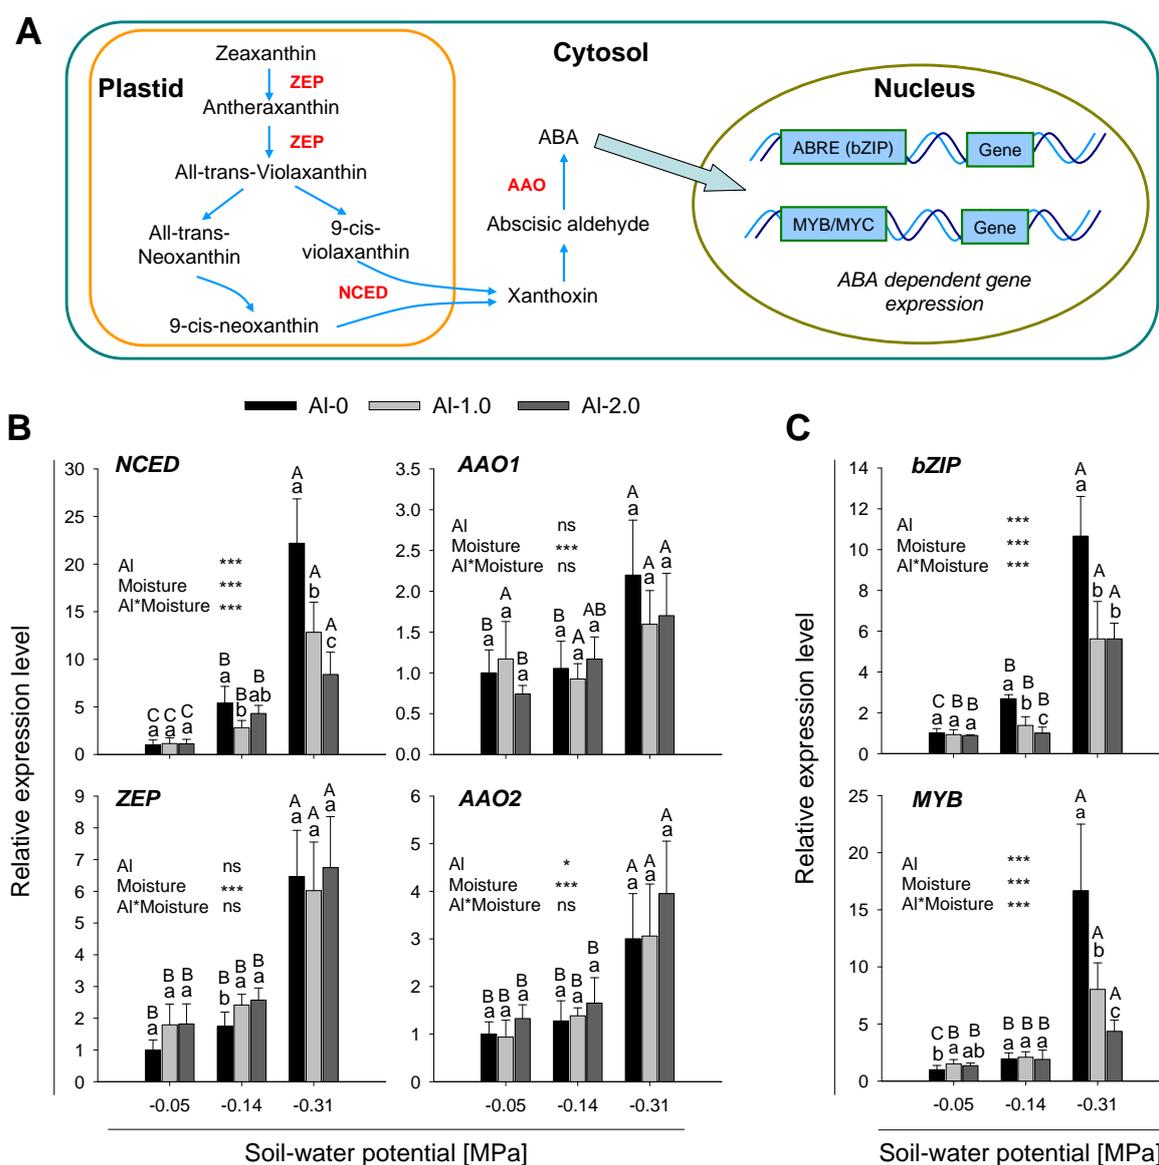

Figure 8 Schematic flow of ABA biosynthesis and ABA-dependent gene-regulation pathways (A) and the expression of genes coding for enzymes involved in the pathways as shown in A (B,C) in 1-cm root tips of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. qRT-PCR was performed using the β -tubulin gene as internal standard. Bars represent means \pm SD, $n = 3$. Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. For the ANOVA, *, *** denote significant differences at $P < 0.05$, $P < 0.001$, respectively. ns = not significant. ZEP, zeaxanthin epoxidase; NCED, 9-cis-epoxycarotenoid dioxygenase; AAO, abscisic aldehyde oxidase; ABRE, ABA-responsive element.

The observed changes in the expression of genes related to ABA biosynthesis and of transcription factors mediating ABA-dependent gene regulation were fully supported by the determination of ABA concentrations in the root tips (Fig. 9). Drought stress alone

greatly increased the ABA concentration. Al supply alone only slightly decreased the ABA concentration in the root tips of well-watered plants. In combination with drought stress Al markedly suppressed the drought-enhanced ABA accumulation in the root tips (highly significant Al x drought interaction).

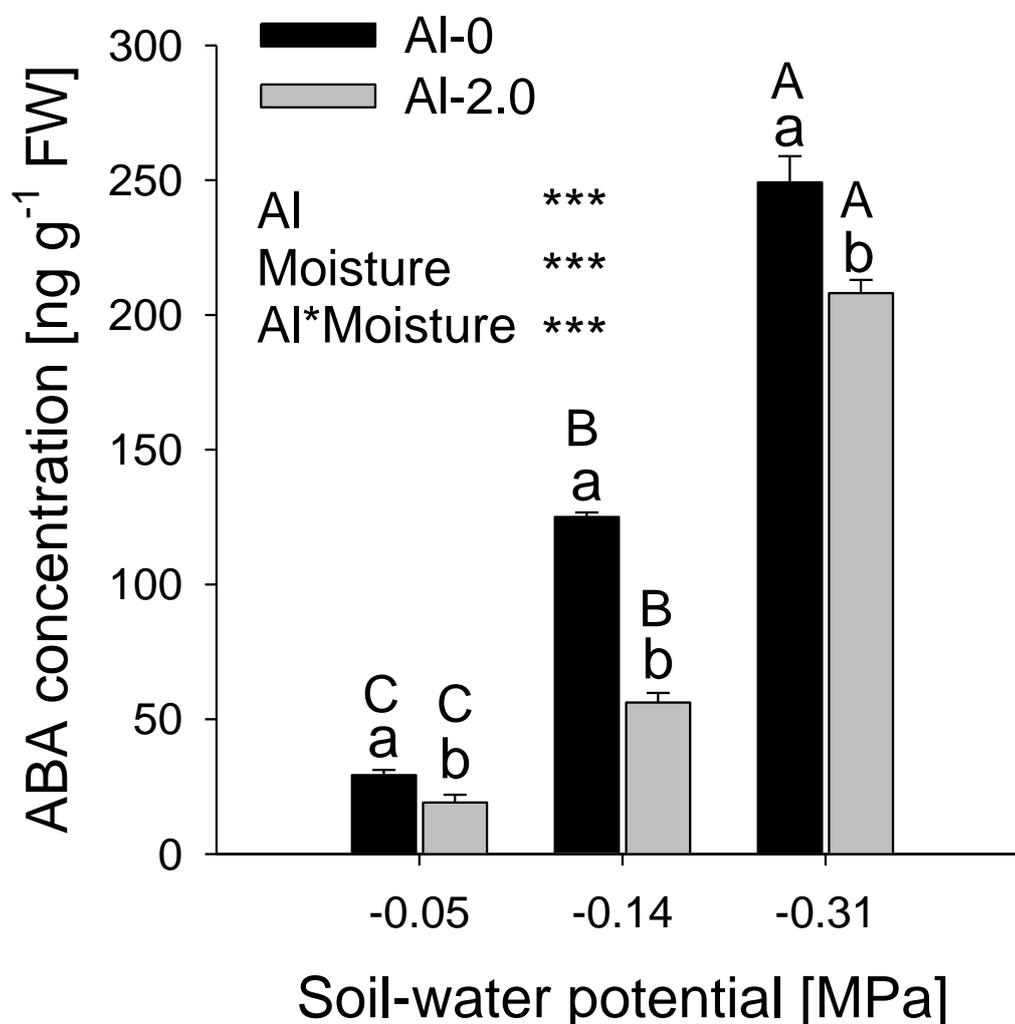

Figure 9 Abscisic acid (ABA) concentration in the 1-cm root tips of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. Bars represent means \pm SD, $n = 3$. Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. For the ANOVA, *** denote significant differences at $P < 0.001$.

In addition to ABA, the concentrations of other phytohormones were analyzed in the root tips. No significant effects of either drought or Al were found on salicylic acid (SA) and jasmonic acid (JA) (Supplemental Fig. S3). Sole Al stress significantly increased, but combined Al and drought stress reversed the Al-enhanced indole-3-acetic acid (IAA)

concentration. However, drought stress significantly increased not only the biologically active zeatin-riboside (ZR) (Fig. 10) but also the trans-zeatin (tZ) (Supplemental Fig. S3) concentrations in the root tips. Among the cytokinin (CK) storage forms only the zeatin-O-glucoside (ZOG) concentration was strongly increased at the lowest soil moisture (Supplemental Fig. S3). In well-watered soil Al did not affect the CK concentrations. However, Al strongly enhanced the drought-increased ZR and ZOG concentrations in the root tips (Fig. 10; Supplemental Fig. S3).

The clear changes in CK concentration prompted the study in the root tips of common bean the expression of the genes *IPT* (adenosine-phosphate isopentenyl-transferase), *CYP735A* (cytochrome P450 monooxygenase 735A) involved in CK biosynthesis and *ZOGT* (zeatin-O-glucosyltransferase), *β Glc* (β -glucosidase) and *CKX* (cytokinin oxidase/dehydrogenase) involved in CK degradation (Fig. 11A). Both drought and Al treatment individually significantly increased the gene expression of all genes except *β Glc* (Fig. 11B). Under combined drought and Al stresses, Al treatment decreased the drought-enhanced expression of all *IPT* genes. The Al-enhanced expression of the *CYP735A*, *ZOGT*, and *CKX* genes in well-watered plants disappeared under reduced soil moisture maintaining the drought-stimulated expression level.

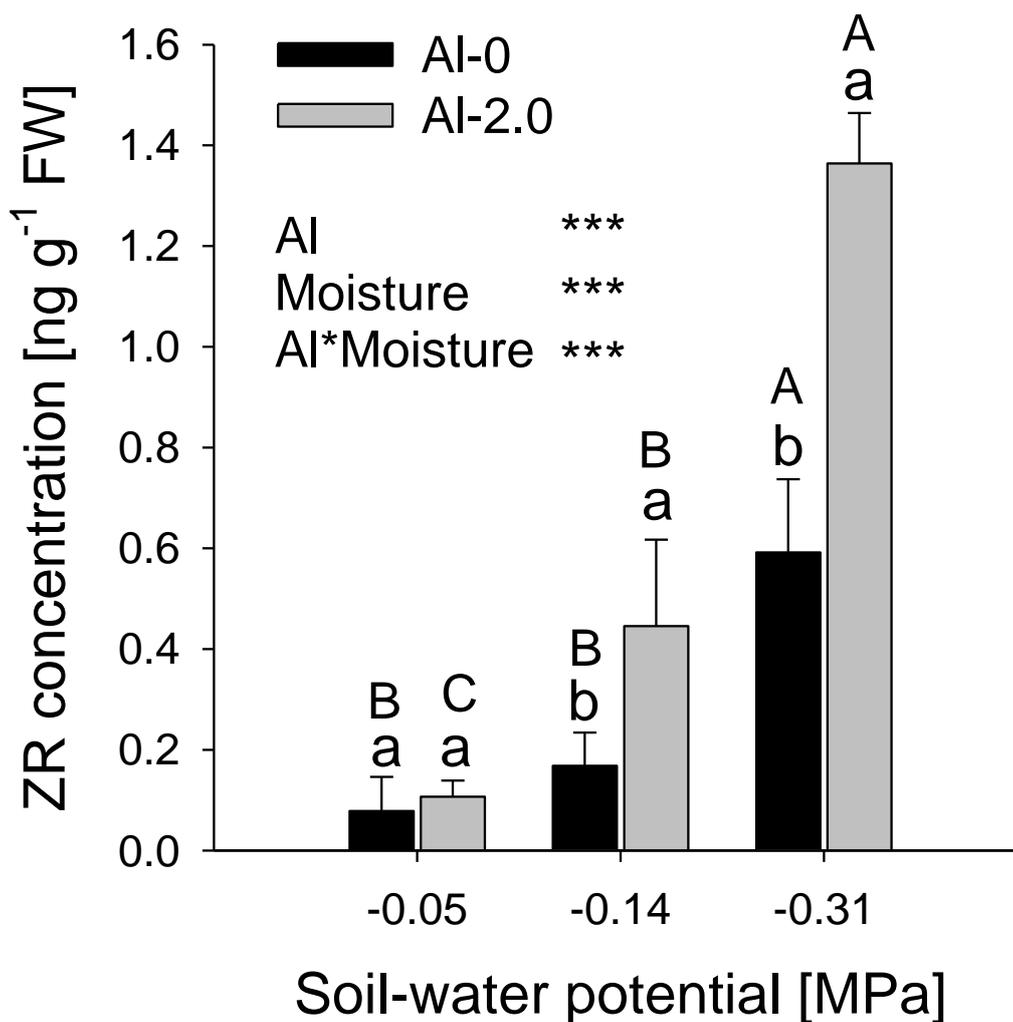

Figure 10 Zeatin riboside (ZR) concentration in the 1-cm root tips of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil 24 h. Bars represent means \pm SD, $n = 3$. Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. For the ANOVA, *** denote significant differences at $P < 0.001$.

Discussion

The main and easily observed symptom of Al toxicity is the rapid inhibition of root growth (Horst et al., 1992; Delhaize and Ryan, 1995; Horst et al., 2010). Plant Al toxicity mainly depends on the soil pH, when the pH drops below 5, Al^{3+} will be released into the soil solution and becomes the main limiting factor of crop production on acid soils (Eswaran et al., 1997). This is supported by the present results: the lower the soil pH the higher the Al toxicity in common bean (Fig. 1). A positive correlation between Al-induced short-term inhibition of root elongation and Al accumulation was found in the root-tip apoplast of common bean (Rangel et al., 2009) indicating that the exclusion of Al from the root tip apoplast is crucial for Al resistance (Horst et al., 2010). Under short-term Al stress, Al accumulates mainly in the root apoplast of common bean (Rangel et al., 2009), where Al^{3+} strongly binds to the negatively charged binding sites (Blamey et al., 1990; Horst et al., 2010). However, under soil conditions, the Al content in the root tip could not reliably be analyzed because of the difficulty to remove soil from the root surface. Although it was suggested that titanium (Ti) can be used as an indicator of soil contamination of plant samples because it is abundant in soil but not in plants (Cook et al., 2009), laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) analysis of root tips showed that titanium can also be absorbed into the root tissue (data not shown). Therefore, our efforts to analyze root Al in the soil-grown plants corrected for soil contamination on the basis of the Ti content failed in this study.

Induction of callose synthesis has been proved to be a sensitive indicator of Al injury in roots (Wissemeier et al., 1987; Staß and Horst, 2009), particularly in the root apex (Wissemeier and Horst 1995; Sivaguru et al., 2006) and has been used as a reliable parameter for the classification of genotypes of different plant species for Al resistance and adaptation to acid Al-toxic soils (Wissenmeier et al., 1992; Horst et al., 1997; Eticha et al. 2005b). In the present study, we confirmed that there was a significantly negatively correlation between the Al-induced inhibition of root elongation and the callose content in the root tips of the Al-sensitive bean genotype VAX 1 (Fig. 2B, E). Since, in addition, a significantly positive linear correlation between the Al-induced callose synthesis and Al concentration in the root tips existed (Fig. 2C) the induction of callose was used in this study as a sensitive and reliable indicator of Al accumulation in the root tips of soil-grown plants. In the present study, PEG 6000-induced osmotic stress reduced the Al content in root tips and thus enhanced the Al resistance in the bean genotype VAX 1 (Fig. 3A, B),

which support our previous results (Yang et al., 2010). The significant suppression of Al-induced callose production in the PEG 6000-treated root tips (Fig. 3C) further confirmed that callose content is a reliable indicator of Al accumulation in root tips and Al toxicity. In soil-grown plants drought reduced the Al-induced enhancement of callose production in the bean root tips (Fig. 4C, Fig. 5B) suggesting that drought in soils as well as PEG 6000 in hydroponics may share the same mechanism in reducing Al accumulation in the root tips and thus Al toxicity.

In contrast to PEG 6000 (Yang et al., 2011), drought also increased the expression of the *ACCO* gene (Fig. 6). Thus it appears that the expression of this gene is not specific to Al. Drought (-0.31 MPa SWP) resulted in a 10-fold up-regulation compared to the well-watered control (WW, no Al). This up-regulation was similar to the 15-fold up-regulation by Al (2.0 g Al kg⁻¹ soil). In contrast to the *ACCO* gene, the expression of the *MATE* gene was rather specific for Al (140-fold increase) compared to drought (10-fold increase). Compared to hydroponics (Eticha et al., 2010; Yang et al., 2011) the Al-induced *MATE* gene expression was less in soil, which can mainly be attributed to a higher basic level of gene expression in the WW limed soil. Drought (-0.31 MPa SWP) significantly reduced the Al-induced expression of the *MATE* gene particularly at the high Al level (2.0 g kg⁻¹ soil) (Fig. 6A), providing further evidence that drought reduces Al toxicity of common bean.

Although the decrease of callose formation and *MATE* gene expression strongly support the view that drought reduces Al toxicity of common bean in soil, Al supply aggravated the drought stress-induced inhibition of root elongation (Fig. 4A, B; Fig. 5A). This result is in contrast to the alleviation of Al-induced inhibition of root elongation by PEG 6000 (osmotic stress) in hydroponics (Fig. 3A; Yang et al., 2010). It thus appears that in soil, Al increases the susceptibility of roots to drought as proposed by Goldman et al. (1989) in soybean. The difference between the two experimental approaches may result from the possibility to adapt to osmotic stress (PEG 6000) in hydroponic culture allowing sufficient water uptake to resume root elongation, whereas in dried soil the adaptation to water deficit fails particularly in presence of Al.

Microarray analysis in *Arabidopsis* has revealed that the drought-induced genes can be classified into two groups (Shinozaki et al., 2003). The first group codes for proteins which probably function in stress tolerance, such as late embryogenesis abundant (LEA) proteins, osmotin, antifreeze proteins, mRNA-binding proteins, key enzymes for osmolyte

biosynthesis, water channel proteins, sugar and proline transporters, detoxification enzymes and lipid-transfer proteins. The second group comprises genes coding for regulatory proteins involved in signal transduction and transcription factors such as *bZIP*, *MYB*, *MYC* and *DREB* (Shinozaki and Yamaguchi-Shinozaki, 2007). Our previous study with common bean in hydroponics using PEG 6000 mimicking drought stress revealed that the osmotic stress-associated genes *P5CS*, *SUS*, *AQP*, *KS-DHN*, *PvLEA18* were significantly up-regulated while *CYP701A* was down-regulated in the root tips under stress (Yang et al., 2011). In the present study the same genes were comparably regulated, with the exception of the *CYP701A* gene which was up-regulated by drought stress in soil (Fig. 7) supporting the use of PEG-6000 in hydroponics in determining short-term drought stress responses of root apices at the molecular level.

The accumulation of ABA in the root tips is necessary to maintain the primary root elongation in maize at low water potentials (Sharp et al., 2004; Yamaguchi and Sharp, 2010). In the current study drought significantly increased the ABA concentration in the root tips of common bean (Fig. 9). AI significantly suppressed this drought-enhanced ABA accumulation suggesting reduced protection of root tips from drought causing aggravated inhibition of root elongation. Three genes encoding zeaxanthin epoxidase (*ZEP*), 9-cis-epoxycarotenoid dioxygenase (*NCED*) and abscisic aldehyde oxidase (*AAO*) involved in the ABA biosynthesis have been identified (Seo and Koshihara, 2002; Fig. 8A). It has been reported that drought increased the gene expression of *ZEP* in tobacco (*Nicotiana plumbaginifolia*) (Audran et al., 1998), tomato (*Solanum lycopersicum*) (Thompson et al., 2000), *NCED* in common bean (*P. vulgaris*) (Qin and Zeevaart, 1999), cowpea (*Vigna unguiculata*) (Iuchi et al., 2000), avocado (*Persea Americana*) (Chernys and Zeevaart, 2000) and barley (*Hordeum vulgare*) (Seiler et al., 2011), and *AAO* in *Arabidopsis thaliana* (Seo et al., 2000). Overexpression of *NCED* in tobacco (*N. plumbaginifolia*) and *Arabidopsis* resulted in an increase in the endogenous ABA level and an improvement of drought tolerance (Iuchi et al., 2001; Qin and Zeevaart, 2002). In this study, the expression of *NCED*, *ZEP*, *AAO1* and *AAO2* genes in the root tips of common bean were significantly up-regulated by drought (Fig. 8B). However, AI reversed the drought-enhanced expression only of the *NCED* gene (Fig. 8B) suggesting that *NCED* is the critical gene in the AI/drought interaction leading to the suppression of drought-induced ABA production in the root apex of common bean. Some hydroponic studies indicated that AI induces ABA production in the root tips of soybean (*Glycine max*), which was supposed to regulate AI resistance mechanisms (Shen et al., 2004; Hou et al., 2010). However, we

found that in common bean AI slightly but significantly reduced the ABA accumulation in the root tips, but had no effect on the expression of genes involved in ABA biosynthesis except *ZEP* which was enhanced by AI treatment (Fig. 8B).

ABA was shown to be involved in the regulation of many water deficit-induced genes (Bray, 1997), in which the ABA-responsive element (ABRE) and the MYB/MYC transcription factor play key roles (Shinozaki and Yamaguchi-Shinozaki, 1997; 2007). The ABRE elements contain a DNA-binding motif of the basic domain/leucine zipper (*bZIP* structure). When ABREs binds to the corresponding bZIP family transcription factors, it can lead to ABA-induced gene expression. Therefore, based on the above information, we speculated that AI might suppress drought-induced ABA-responsive genes expression via decreasing the regulation of ABA-dependent transcription factors such as bZIP and MYB, and thus reduce the drought tolerance of the root (Presented in Fig. 12). As expected, in this study, the expression of the two transcription factor genes, *bZIP* and *MYB*, were significantly enhanced by drought in the root tips of common bean (Fig. 8C), which was in agreement with the osmotic stress (PEG 6000)-induced expression of both genes in common bean (Yang et al., 2011). Consistent with the change in *NCED* gene expression and ABA accumulation in the root tips, AI reversed the drought-elevated gene expression of *bZIP* and *MYB* (Fig. 8C). A number of studies have demonstrated that the induction of bZIP and MYB transcription factors play a key role in drought-induced gene expression and drought tolerance. For example, Uno et al. (2000) reported that the ABA-mediated induction of the dehydration-responsive Arabidopsis gene, *rd29B*, via phosphorylation of a protein kinase requires two ABREs and two bZIP transcription factors (AREB1 and AREB2). Transgenic rice over-expressing *OsbZIP23* showed significantly improved tolerance to drought and sensitivity to ABA, while the *Osbzip23* mutant showed significantly decreased sensitivity to ABA and decreased drought tolerance (Xiang et al., 2008). Rodriguez-Urde and O'Connell (2006) found a root specific bZIP transcription factor responsive to water deficit in tepary bean (*Phaseolus acutifolius*) and common bean (*P. vulgaris*) which may allow the plant to maintain root elongation. The MYB and MYC elements were defined from the analysis of an Arabidopsis drought-inducible gene, *rd22*, involved in regulating the expression of ABA-induced genes in response to severe water-deficit stress (Abe et al., 1997). In Arabidopsis, Seo et al. (2009) observed that the R2R3-type MYB transcription factor, MYB96, regulated drought stress response by integrating ABA and auxin signals. The *MYB96*-overexpressing *A. thaliana myb96-ox* mutant exhibited enhanced drought resistance with reduced number of lateral roots,

whereas the *myb96-1* mutant was more susceptible to drought, suggesting that *MYB96* is a molecular link that mediates the ABA-auxin crosslink in the drought-stress response.

The accumulation of osmotically active compounds, such as sucrose and proline, has been considered as one of the crucial processes for osmotic adjustment in plant cellular adaptation to drought (Chaves et al., 2003). In the resurrection plant *C. plantagineum*, the sugar octulose was rapidly converted into sucrose during dehydration (Bianchi et al., 1991), and this sugar conversion was coupled with an increased expression of the $\Delta 1$ -pyrroline-5-carboxylate synthase (*P5CS*), sucrose synthase (*SUS*) and sucrose-phosphate synthase (*SPS*) genes (Ingram et al., 1997; Rodriguez et al., 2010). Dehydration-induced enhanced expression of the *SUS* gene was also found in other species such as maize (Zheng et al., 2004; Spollen et al., 2008). *SUS* plays a major role in sucrose biosynthesis, which catalyses a reversible reaction $\text{UDPGlc} + \text{fructose} \rightleftharpoons \text{sucrose} + \text{UDP}$. Whether the up-regulation of *SUS* contributes to the synthesis (Geigenberger and Stitt, 1993; D'édardin et al., 1997) or degradation (Heim et al., 1993) of sucrose is still not well known. But it appears that the physiological significance of a rapid cycling of sucrose for stressed-cells is an enhanced carbon partitioning in favour of sucrose accumulation for osmoregulation (Wang et al., 2000). *P5CS* is the enzyme which catalyzes conversion of pyrroline-5-carboxylic acid (*P5C*) to proline in plants (Kishor et al., 2005). Ooho et al. (2003) found that dehydration and rehydration rapidly up-regulated and repressed the gene expression of *P5CS* in *Arabidopsis*, respectively, which was supported by our previous study on PEG-induced osmotic stress in common bean (Yang et al., 2011). Overexpression of the *P5CS* gene in various plants resulted in elevated proline production and improved OS tolerance (reviewed by Bartels and Sunkar, 2005).

Aquaporins (AQPs) facilitate water transport through cellular membranes, and thus play major roles in water homeostasis (Alexandersson et al., 2010). Genes encoding AQPs show distinct responses to drought. For example, in *Arabidopsis* the transcripts of the plasma membrane intrinsic protein (PIP) (one subfamily of AQPs) were down-regulated by drought, with the exception of *AtPIP1;4*, *AtPIP2;5* (up-regulated) and *AtPIP2;6* (unaffected) (Alexandersson et al., 2005). Upon osmotic stress, *OsPIP1;3* was up-regulated in upland rice that has better drought resistance compared to lowland rice, in which *OsPIP1;3* did not show any change in expression (Lian et al., 2006). A positive response of the AQP gene to drought may trigger higher water permeability and facilitate water flux, while a negative response may result in decreased membrane permeability and allow cellular water conservation (Bartels and Sunkar, 2005).

Late embryogenesis-abundant (LEA) proteins are well known to play crucial roles in cellular dehydration tolerance (Ingram and Bartels, 1996; Hundertmark and Hinch, 2008). In common bean, it has been found that the expression of the *PvLEA18* gene was highly induced particularly in roots by water deficit (Colmenero-Flores et al., 1999). The *PvLEA18* gene was found to be up-regulated by PEG 6000 in root tips of common bean according to a transcriptomic study using SuperSAGE library (Yang et al., 2011) which was supported by the present study (Fig. 7).

The cytochrome P450s superfamily (CYP) is a large and diverse group of enzymes and may serve as monooxygenases involved in the biosynthesis of metabolites conferring abiotic stress tolerance (Schuler and Werck-Reichhart, 2003). In common bean, the expression of a *CYP701A* gene belonging to the *CYP* family and homologue to soybean (*G. max*) *CYP701A16* was up-regulated by drought (Fig. 7), but it was down-regulated by PEG-induced osmotic stress (Yang et al., 2011). The role of this gene in drought tolerance is not well understood. The different response of the *CYP701A* gene to drought and PEG stress may indicate that the response to drought and PEG may involve different molecular responses.

The modification of cell-wall extension properties has been shown to be one of the mechanisms of the response of maize primary root growth to water deficit (Sharp et al., 2004; Yamaguchi and Sharp, 2010). Thus, besides the osmotic stress-associated genes, in this study, six cell wall-associated genes (*BEG*, *HRGP*, *PRP*, *XTHa*, *XTHb* and *LTP*) were also selected from our transcriptomic analysis (SuperSAGE) of PEG-induced gene expression in common bean (Yang et al., 2011). The PEG 6000-induced reduction of Al accumulation has been related to the reduction of cell-wall porosity (Yang et al., 2010). In this study, quantitative Real-Time-PCR (qRT-PCR) analysis demonstrated that the differential expression of these six cell wall-associated genes by drought were similar with their response to PEG (Fig. 7; Yang et al., 2011). Thus, it appears that the drought-induced reduction of Al toxicity, which is indicated by the suppression of Al-enhanced callose production and *MATE* gene expression in the root tips (Fig. 4, Fig. 5, Fig. 6), might also result from drought-induced alteration of cell-wall structure. Reduced expression of the *XTHa*, *XTHb* and *BEG* genes and increased expression of the *HRGP* gene might contribute to PEG-induced reduction of cell-wall porosity in common bean. XTH (xyloglucan endotransglucosylase/hydrolase) and BEG (Glucan endo-1, 3-beta-glucosidase) are two cell wall loosening enzymes involved in cleavage or degradation of cell-wall polymers (Rose et al., 2002; Bray, 2004; Minic and Jouanin, 2006). Nieuwland et al. (2005) reported

that *LTP* (lipid transfer proteins) enhanced cell-wall extension causing non-hydrolytic disruption of the cell wall in tobacco. Therefore, in this study with common bean, the increased expression of the *LTP* gene (Fig. 7) may contribute to the maintenance of root elongation of common bean under drought stress. A1 treatment reduced the drought-enhanced expression of the *LTP* gene (Fig. 7) thus enhancing the inhibition of root elongation by combined drought/A1 stresses by reducing cell-wall extensibility.

It has been reported that most genes encoding LEA proteins in Arabidopsis had ABRE elements in their promoters and were induced by ABA. Among these, two genes (*At2g23110*, *At2g23120*) belong to the *PvLEA18* group. Dehydrins (DHNs) is the second biggest group of LEA proteins (Hundertmark and Hinch, 2008). The EST of the *KS-DHN* gene in common bean has high sequence similarity to the *At1g54410* gene which belongs to the DHN group of LEA proteins and also can be induced by ABA (Hundertmark and Hinch, 2008). In tomato (*S. lycopersicum*), over-expression of the drought-induced *SLAREB1* gene up-regulated the genes encoding LTP and LEA proteins (Orellana et al., 2010). Moreover, Saftner and Wyse (1984) observed that ABA increased sucrose uptake in the roots of sugar beet (*Beta uldgaris*), and the ABA-insensitive (*abi8*) mutant showed a strong reduction of the expression of the *SUS* gene in Arabidopsis (Brocard-Gifford et al., 2004). In this study, the A1 suppression of the drought-induced gene expression of *SUS*, *PvLEA18*, *KS-DHN* and *LTP* in the root tips of common bean (Fig. 7) was consistent with the reduction in expression of the *NCED* gene (Fig. 8B) involved in ABA biosynthesis and thus ABA accumulation (Fig. 9) and of the two transcription factors *bZIP* and *MYB* (Fig. 8C) involved in the regulation of ABA-dependent genes under drought stress.

Several studies have clearly shown that ABA can suppress ethylene production, and the maintenance of root elongation under water-deficit conditions requires increased ABA levels to prevent excess ethylene production (Sharp et al., 2000; Spollen et al., 2000; Sharp, 2002; LeNoble et al., 2004). Cytokinin (CK) stimulates ethylene biosynthesis (Chae et al., 2003) and ethylene mediated the CK-induced inhibition of root elongation as observed in pea (*Pisum sativum*) (Bertell and Eliasson, 1992), Arabidopsis (Cary et al., 1995; Růžička et al., 2009) and common bean (Massot et al., 2002). It was reported that ethylene and CKs strongly inhibit root growth (Werner et al., 2001; Stepanova et al., 2007; Swarup et al., 2007). Up to now, little evidence exists on the direct effect of ABA on CKs. However, Jelić and Bogdanović (1988) reported that ABA inhibited the CK-stimulated synthesis of chlorophyll in the light in *Pinus nigra*. Ding et al. (2008) found that ABA could suppress CK activation of cell division in the roots of *Medicago truncatula*. Vysotskaya et al. (2009)

supposed that ABA could regulate shoot CK concentrations via mediating the activity of cytokinin oxidase/dehydrogenase (CKX) involved in the CK biosynthesis; Takei et al. (2004) observed that ABA treatment highly reduced the expression of the CK biosynthesis genes *CYP735A1* and *CYP735A2* in Arabidopsis. Therefore, the cross-talk between these phytohormones revealed a potential regulatory mechanism of Al-reduced drought resistance in common bean (presented in Fig. 12): the Al-suppressed drought-induced ABA accumulation in the root tips may promote CK production, subsequently stimulate synthesis of ethylene, and thus enhance inhibition of root elongation. Furthermore, we also observed that Al enhanced the drought-induced expression of the *ACCO* gene (Fig. 6) in agreement with the enhanced inhibition of root elongation at combined Al and drought stresses (Fig. 5A). It is well known that ACCO catalyzes the last step in the biosynthesis of ethylene in plants (Wang et al., 2002).

According to the above speculation, we further analysed the concentrations of other phytohormones in the root tips of common bean, such as different forms of CKs, IAA, SA and JA (Supplemental Fig. S3). Of these phytohormones, drought only significantly increased the concentrations in the root apices of the biologically active CK forms, particularly zeatin riboside (ZR) (Fig. 10) and *trans*-zeatin (tZ) (Supplemental Fig. S3). Al greatly enhanced the drought effect on the concentrations of ZR and of zeatin-O-glucoside (ZOG) which is the major CK storage form (Supplemental Fig. S3). Although the specific role of ZR in root elongation is not yet known, its increased accumulation in the root tips (Fig. 10) particularly under combined drought/Al stress may be involved in the aggravated inhibition of root elongation (Skoog and Miller, 1957; Cary et al., 1995; Werner et al., 2001). Moreover, we found that there was no Al effect on the SA synthesis in the root tips of bean, though Yang et al. (2003) observed that SA induced Al resistance by modulation of citrate exudation from roots of *Cassia tora*. The difference may depend on the species or the Al stress conditions. However, we found that sole Al treatment increased the IAA concentration in the root tips of bean while subsequently was suppressed by drought (Supplemental Fig. S3), which may support the results that drought reduced Al toxicity.

The genes *IPT* (adenosine-phosphate isopentenyl-transferase), *CYP735A* (cytochrome P450 monooxygenase 735A), *CKX*, *ZOGT* (zeatin-O-glucosyltransferase) and *β Glc* (β -glucosidase) encoding the proteins involved in the biosynthesis of CKs have been identified (Sakakibara, 2006; Kudo et al., 2010; Fig. 11A). Transgenic studies have demonstrated that these genes affect root growth by changing the CKs level in the root tissues. For example, using a transactivation system overexpression of the *IPT* gene in

Arabidopsis (Kuderová et al., 2008) enhanced the levels of biologically active CKs and inhibited primary root elongation. Over-expression of the *ZOGT* gene in maize (Pineda Rodo et al., 2008), the *CKX* gene in Arabidopsis (Werner et al., 2010) and tobacco (Werner et al., 2001; Werner et al., 2010) resulted in enhanced root growth and branching. It appears that not only the primary root but also the lateral root growth is seriously inhibited by CKs. In the current study, the inhibition of both primary and lateral root growth in common bean by drought and Al (Al plus drought > drought > Al > control) is clearly shown in Fig. 4A. Werner et al. (2010) reported that the root-specific reduction of CK by overexpression of the *CKX* gene strongly enhanced drought resistance in Arabidopsis and tobacco. In the present study, both drought and Al treatment significantly increased the expression levels of the *IPT*, *CYP735A*, *ZOGT* and *CKX* genes but not of the *βGlc* gene which catalyze the de-glycosylation of CKs (Fig. 11A) in the root tips of common bean (Fig. 11B). However, although drought reduced Al toxicity as described above, it did not reduce the Al-induced gene expression of *CYP735A*, *ZOGT* and *CKX* (Fig. 11B), suggesting that the *CYP735A* and *ZOGT* genes play key roles in Al-enhanced drought-induced ZR and ZOG accumulation, respectively, in the root tips of common bean (Fig. 10; Supplemental Fig. S3). The maintenance of the expression of the *ZOGT* and *CKX* genes, responsible for the glycosylation and degradation of CKs, respectively (Fig. 11A), may play a role in the rescue of the roots from ZR-induced growth inhibition by degradation or deactivation and maintenance of optimal levels of CKs (Werner et al., 2001). No Al effect on CK concentrations was found in the root tips (Fig. 11B), although Al alone significantly increased the expression of most CK biosynthetic genes indicating that the synthesized CKs were transported from the root tips to other plant organs. It was reported that CKs transported to the shoot function as a long-distance regulatory signal (Kudo et al., 2010) contributing to maintaining shoot growth (Werner et al., 2001) under Al stress.

In conclusion, taken together the results from this study suggest that low soil moisture leading to drought stress alleviates Al toxicity based on less Al-induced callose formation and lower expression of a *MATE* gene in the root tips of the Al-sensitive bean genotype VAX 1. However, Al treatment increased the susceptibility of the root apex to drought by aggravating drought-induced inhibition of root elongation resulting from the disruption of the gene regulatory network involved in the ABA signal transduction and the ABA signal cross-talk with other phytohormones that are necessary for maintaining root growth under drought stress.

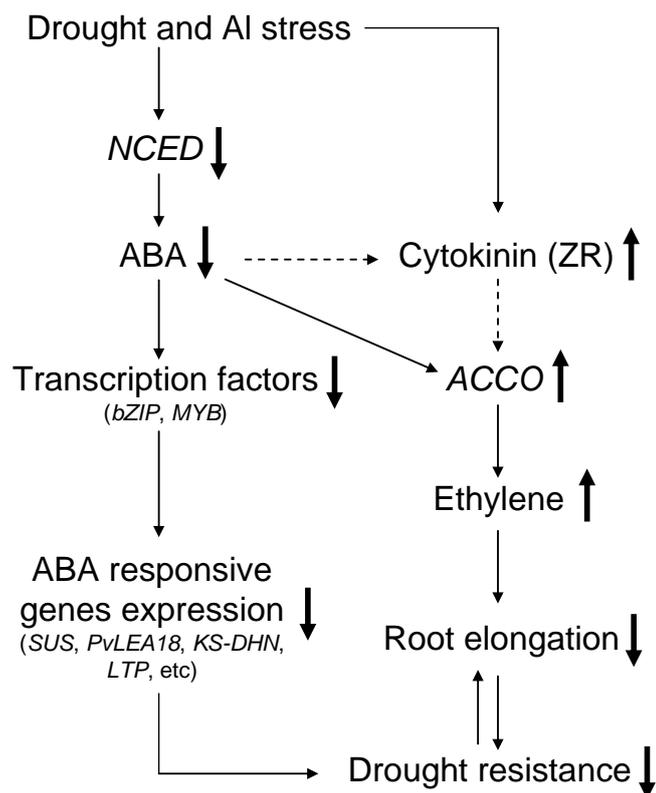

Figure 12 Schematic representation of the potential regulatory mechanisms of combined drought and Al stress in common bean. The thick arrows indicate the up- and down-regulated changes. The thin dashed arrows indicate the potential connections. For further explanations see the related discussion

GENERAL DISCUSSION

Much progress has been made during recent years in the physiological and molecular understanding of the response of plants roots to the individual aluminium and drought stress (see reviews, Kochian et al., 2004; Ma, 2007; Ryan and Delhaize, 2010; Horst et al., 2010; Ryan et al., 2011; Wu and Cosgrove, 2000; Sharp et al., 2004; Moore et al., 2008; Yamaguchi and Sharp, 2010). Generally, the inhibition of root elongation is thought to be the primary symptom of Al toxicity and the root apex is the most Al-sensitive root zone (Kochian et al., 2004; Horst et al., 2010; Ryan et al., 2010). In common bean, Rangel et al. (2007) found that the response of root elongation to Al in the genotypes Quimbaya (Al-resistant) and VAX 1 (Al-sensitive) was characterized by a similar initial period (4 h) of Al sensitivity followed by a contrasting recovery period (8 - 25 h), and both the transition zone (TZ, 1-2 mm) and elongation zone (EZ, 2-10 mm) are targets of Al injury. Mechanisms of Al resistance have been established in common bean to be related to a lower Al accumulation in the root tip resulting from the Al-induced citrate exudation from the root apex (Rangel et al., 2009; 2010). However, in contrast to Al, the traits for evaluation of drought resistance have not yet been established. In plants growing in dry soil, both shoot and root growth is hampered (Westgate and Boyer, 1985; Sharp et al., 1988), while an important feature of the root response to drought is the ability of some roots to continue elongation under water deficit conditions that may have completely inhibited shoot growth (Sharp et al., 2004). The maintenance of root growth during water deficit facilitates water uptake from the subsoil (Sponchiado et al., 1989; Serraj and Sinclair, 2002). However, in acid soils under low soil-moisture conditions (dry spells), Al toxicity may strongly restrict the roots to exploit water from the subsoil. This hypothesis was strongly supported by our studies performed in acid, Al-toxic soil under low moisture (see Chapter 4), but not in PEG-simulated drought (osmotic) stress conditions in hydroponics (see Chapter 1 and 2). The current studies provide better comprehensive understanding and a set of novel insights into the physiological and molecular mechanisms of Al and drought resistance, and are important to clarify the opportunities and constraints in breeding for adaptation to multiple abiotic stresses.

PEG-simulated drought (osmotic) stress improves aluminium resistance in common bean

In common bean, a positive relationship between Al-induced short-term inhibition of root

elongation and Al accumulation in the root tip apoplast was found (Rangel et al., 2009). Our present study indicated that PEG ameliorated Al-inhibited root elongation by reducing Al accumulation in the root tips (Fig. 1 in Chapter 1), suggesting that PEG improved Al resistance of common bean. The PEG-induced reduction of Al accumulation in the root tips was not due to complexing or precipitating Al in the treatment solution because PEG did not affect the concentration of mononuclear phytotoxic Al in the treatment (+Al+PEG) solution (see Materials and methods in Chapter 1). The apoplast of the root apex has been proposed to be the primary site of Al injury and plays an important role in Al resistance (Horst, 1995; Horst et al., 2010). The density of the negative charge carried by the CW is determined by the pectin content and the degree of methylation of pectin which thus determines the Al binding capacity of roots (Schmohl et al., 2000; Eticha et al., 2005; Yang et al., 2008). About 80% of the total Al in the root tips of common bean was bound in the CW (Rangel et al., 2009). Our study with common bean showed that PEG did not reduce Al accumulation by decreasing the CW negativity since no PEG effect on the unmethylated pectin content of root apices was found (Fig. 4 in Chapter 1).

Citrate exudation contributes to Al resistance of common bean by excluding Al from the root apex (Rangel et al., 2010). Further studies by Eticha et al. (2010) indicated that the expression of a *MATE* gene was crucial for Al-induced citrate exudation and thus Al resistance. However, in contrast to sorghum (Magalhaes et al., 2007) and barley (Furukawa et al., 2007), where the expression level of the *SbMATE* and *HvMATE* genes decided on the genotypic variation in Al resistance the expression of the *MATE* gene in common bean can not explain genotypic differences in Al resistance. The expression of the *MATE* gene only was a prerequisite for citrate exudation, genotypic Al resistance in common bean mainly depended on the capacity to sustain the synthesis of citrate for maintaining the cytosolic citrate pool that enabled exudation (Eticha et al., 2010; Rangel et al., 2010). The present study demonstrated that Al stress significantly increased citrate exudation from root apices during the early Al injury period (3–9 h), but the exudation was reduced with time because of the reduction of citrate content in the root apex (Fig. 2 and Fig. 3 in Chapter 1), confirming that the citrate exudation was related to the synthesis of citrate in the root apex (Rangel et al., 2010). However, no positive effect of PEG on Al-induced citrate exudation from root apex was found (Fig. 3 in Chapter 1) though PEG enhanced the Al-suppressed citrate content in the root apical tissues (Fig. 2 in Chapter 1). Considering that the removal of PEG from the treatment solution rapidly restored the Al accumulation capacity of the root apices (Fig. 5 in Chapter 1), the contribution of citrate exudation in reducing the Al

binding capacity in presence of PEG cannot be unequivocally ruled out. On the other hand, PEG did not induce citrate exudation from the root apex, although it highly increased the citrate content in the root apical tissues (Fig. 2 in Chapter 1). Thus, the lack of citrate exudation under PEG stress may largely depend on the lack of the *MATE* gene expression (Fig. 3 in Chapter 2).

Eticha et al. (2010) observed that the initial Al-induced inhibition of root elongation was correlated with the expression of an *ACCO* gene in both bean genotypes, Quimbaya (Al-resistant) and VAX 1 (Al-sensitive). It has been speculated that the Al-induced inhibition of root growth is due to enhanced gene expression and enzyme activity of ACCO resulting in increased ethylene production in *Lotus japonicus* and *Medicago truncatula* (Sun et al., 2007). In this study, a significant correlation among *MATE* and *ACCO* gene expression, root elongation and the Al concentration in the root tips of common bean was found (Fig. 2 in Chapter 2), and PEG treatment alone had no effect on the expression of both genes (Fig. 3 in Chapter 2) providing opportunities to further clarify the PEG-induced reduction of Al accumulation in the root tips and Al-induced inhibition of root elongation using the expression of the *MATE* and *ACCO* genes as sensitive indicators of Al toxicity. As expected, the OS-induced exclusion of Al from the root apex and the improvement of root growth were accompanied by a decrease in gene expression of *MATE* and *ACCO* (Fig. 3 in Chapter 2) confirming that OS reduces Al injury.

Water is the most abundant component of the CW making up about two thirds of the wall mass in growing tissues (Cosgrove, 1997). Loss of water from the wall matrix can result in serious disruption to polymer organization (Moore et al., 2008). One obvious effect is that polymers usually well separated in the hydrated wall are brought in close proximity to each other, thus causing polymer adhesion or cross-linking under water stress (Fig. 9A in Chapter 2; Moore et al., 2008). In the present study, the findings that the removal of PEG from the treatment solution quickly (within 15 min) recovered the Al accumulation in the intact root tips (*in vivo*, Fig. 5 in Chapter 1) but not in the isolated ethanol-insoluble CW (*in vitro*, Fig. 8A in Chapter 1) prompted us to further explore the potential involvement of CW structure alteration in PEG-induced reduction of Al accumulation. Using La, Sr and Rb as a tracer of Al, Ca and K, respectively, we found that in comparison with La, Sr, and Rb, the strong reduction of cation accumulation in the root apex and isolated CWs by osmotic stress appears to be specific to Al (Fig. 5, Fig. 7, Fig. 8 and Fig. 9 in Chapter 1). The specificity of cation accumulation might be related to the hydrated ionic radius of the cations: Al^{3+} (0.475 nm) > La^{3+} (0.452 nm) > Sr^{2+} (0.412 nm)

= Ca^{2+} (0.412 nm) > K^+ (0.331 nm) > Rb^+ (0.329 nm) (Nightingale, 1959). Since the pore size of the CW controls the apoplastic transport of water, ions, metabolites and proteins (Carpita et al., 1979; Brett and Waldron, 1996; Cosgrove, 2005), the differences between the ions in Al accumulation of the PEG-exposed root apices and isolated CWs may suggest that PEG (osmotic stress) affects CW porosity. After physically destroying the structure of the CW isolated from PEG-treated root tips, Al binding to the CW was almost restored (Fig. 10 in Chapter 1). In addition, the extent of water loss from the apoplast and consequently shrinkage of the root structure appeared to be dependent of the molecular size of the applied PEG: PEG 6000 > PEG 3000 >> PEG 1000 (Fig. 6 and Fig. S2 in Chapter 1). The higher the hydrodynamic radius the better the exclusion from the apoplast and consequently the dehydration of the apoplast.

Potential roles of genes/proteins related to modification of CW structure in PEG-induced reduction of aluminium accumulation in the root apex

Since the restoration of the Al accumulation capacity of the CWs after the cessation of the PEG stress could only be observed in living root apices (Fig. 5 in Chapter 1) but not in ethanol-insoluble CW material isolated from root apices pre-treated with PEG (Fig. 8A in Chapter 2), a role of enzymes mediating the suppression of Al accumulation has to be postulated. Several CW proteins/enzymes are believed to play important roles in modifying the wall network and thus, possibly, the CW's ability to extend, such as expansin, xyloglucan endotransglycosylase (XET), glucanase (Wu and Cosgrove, 2000). Therefore, the identification of genes/proteins particularly involved in CW modification appeared to be necessary for a better understanding of PEG-induced reduction of root-tip Al accumulation.

First, we conducted the transcriptomic analysis of PEG-stressed root tips using SuperSAGE and confirmed the reliability of this technique by qRT-PCR using 46 differentially expressed genes (Fig. 7 in Chapter 2). Total 611 up- and 728 down-regulated genes in PEG-treated root tips were identified (Fig. 6 and Table S2 in Chapter 2). Among these osmotic stress-regulated genes, CW synthesis and organization-related genes were mostly down-regulated (Fig. 6 in Chapter 2) providing an opportunity to identify genes involved in the OS-induced alteration of CW porosity. Similarly, in *Arabidopsis*, Bray (2004) found that water deficit consistently down-regulated the expression of genes involved in CW synthesis and modification. Structural proteins such as HRGP, glycine-rich protein, and proline-rich proteins are main components of the growing plant CW, and they

can rapidly be insolubilized in the CW during stress condition, such as upon wounding (Showalter, 1993; Cosgrove, 1997). The HRGP proteins are particularly abundant in dicots compared to other structural proteins (Showalter, 1993). In the present study, we found that the expression of a *HRGP* gene was significantly enhanced by OS, and withdrawing of OS rapidly restored the expression of this gene (Fig. 8 in Chapter 2). Thus the role of the *HRGP* gene appears to be important in the OS-induced modification of the CW in common bean. Once the HRGP is secreted into the CW, it will be rapidly insolubilized. The insolubilization of HRGP may be mediated by water deficit-induced enhancement of formation of hydrogen peroxide catalyzed by a CW peroxidase. This response is thought to be an ultra-rapid stress-response reaction that serves to further strengthen the cell wall (Showalter, 1993; Zhu et al., 2007). Osmotic stress-induced physical shrinkage of the CW and thus resulting in a reduction of CW porosity may be further enhanced by the deposition of other CW components, such as structural proteins as schematically depicted in Fig. 9A (Chapter 2). The increased deposition of HRGP proteins in the CW may increase the cross-link between HRGP proteins and other CW components, such as pectins (Showalter, 1993), which was the decisive factor of CW porosity (Baron-Epel et al., 1988), and further reinforce a cell-wall barrier for AI transport into and in the apoplast (Fig. 9B in Chapter 2).

The shrinkage of the CW resulting from PEG 6000-induced dehydration of the apoplast causes adhesion and cross-linking of wall polymers through hydrogen bonding. This bonding will be enhanced by removal of water from the apoplast and is likely to cause an irreversible bonding between polymers resulting in altered biophysical CW properties (Fig. 9A in Chapter 2; Moore et al., 2008), unless some CW loosening or modifying proteins/enzymes were re-induced/activated. The enzyme XTH has been supposed to play key roles in the response to water deficit by modifying the CW structure and extensibility through the cleavage and reformation of bonds between xyloglucan chains (Rose et al., 2002; Wu and Cosgrove, 2000; Bray, 2004; Sharp et al., 2004; Moore et al., 2008). Transcriptomic and proteomics studies have demonstrated that several *XTH* genes were down-regulated by water deficit (Bray, 2004; Zhu et al., 2007). In the present study, qRT-PCR results showed that the expressions of *XTHa* and *XTHb* genes in the root tips of common bean were significantly reduced by PEG-induced dehydration of the apoplast (Fig. 8 in Chapter 2). Withdrawal of PEG from the pre-treatment solution rapidly allowed the recovery of the expression level of the *XTHa* gene (Fig. 8 in Chapter 2), supporting the view that the *XTHa* gene may be involved in the CW modification during the recovery of the apoplast from dehydration (Fig. 9B in Chapter 2). Similar results were found in the

PEG-induced expression of the *CaXTH1* gene in Chickpea (*Cicer arietinum*) (Romo et al., 2005).

Besides the *XTH* and *HRGP* genes, the *BEG* gene may also play an important role in the OS-induced CW modification and thus influencing AI accumulation in the root tips in the present study (Fig. 9B in Chapter 2), since PEG-induced OS significantly reduced the expression of the *BEG* gene, and removal of PEG rapidly restored its expression (Fig. 8 in Chapter 2). BEGs belong to the family of 17 plant glycoside hydrolases, and molecular studies suggested that this enzyme shares a common ancestry with beta-1,3-1,4-glucanase (Minic and Jouanin, 2006; Borad and Sriram, 2008) an abundant protein in all higher plants. They are known to be involved in pathogen defense as well as a wide range of normal developmental processes. They can hydrolytically cleave the 1,3- β -linked glucans, a major component of the fungal CW (Minic and Jouanin, 2006). Although the functions of this enzyme in plant CW modification have not yet been established, a potential role in the OS-induced reduction of CW porosity cannot be ruled out.

In this study, large scale proteomic analysis was not successful in identifying OS-induced proteins involved in CW structure modification in the root tips of common bean as expected. The separation of overlapping protein spots, the recovery of sufficient amounts of proteins and the establishment of an extraction method for CW proteins are still challenges for future proteomics studies. In spite of this, one protein called dehydrin, which has been supposed to play important roles in avoiding irreversible disruption of the CW structure during drought stress (Layton et al., 2010), was significantly increased by OS in the present study (Fig. 6 and Table 4 in Chapter 3). Dehydrins are highly specialized proteins that lack a fixed three-dimensional structure and have evolved to maintain their disordered character under conditions such as water deficit, in which unfolded states of several globular proteins would tend to collapse (Mouillon et al., 2008). Therefore, the OS-elevated abundance of dehydrins in the root tips of common bean may protect the CW from irreversible disruption by PEG-caused CW dehydration, maintain the elastic extension (reversible stretching) properties of the CW, and thus allow the quick recovery of CW extensibility and AI accumulation of the root tips after the removal of osmotic stress. Future research is necessary to clarify the cell localization of dehydrin and its possible role in CW modification.

The interaction between aluminium toxicity and PEG-simulated drought stress in hydroponics is different from the aluminium/drought interaction in soil

PEG-simulated drought strongly reduced Al accumulation and thus enhanced the Al-inhibited root elongation (Fig. 1 in Chapter 1; Fig. 1 in Chapter 2, Fig. 3A, B in Chapter 4). However, in contrast, in dried acidic soils, combined Al toxicity and drought stress resulted in more severe inhibition of root elongation beyond the effects of the individual stresses (Fig. 4A, B, Fig. 5A in Chapter 4). The enhanced inhibition of root elongation was not due to the increased Al toxicity in the root tips. In contrast, a significant reduction of callose formation (Fig. 4C, Fig. 5B in Chapter 4) and *MATE* gene expression (Fig. 6A in Chapter 4) in the root tips strongly suggest amelioration of Al stress. However, obviously the residual Al effect indicated by still slightly higher callose formation and expression of the *MATE* gene (Fig. 6A in Chapter 4) was sufficient to interact with the drought resistance of the root apex leading to enhanced inhibition of root elongation. This Al toxicity-enhanced inhibition of root growth under drought may restrict water uptake of the root from deeper soil layers and thus impede withstanding drought (Fig. 1, this chapter).

It is well known that ABA is produced under water-deficit conditions and plays an important role in the response of plants to drought. The accumulation of ABA in the root tips has been shown to be required for the maintenance of maize primary root elongation at low water potentials (Sharp, 2002; Sharp et al., 2004; Yamaguchi and Sharp, 2010). The main contribution of ABA to drought resistance is the involvement in the regulation of drought-induced genes (Bray, 1997; 2002): the transcription factor bZIP and MYB are responsible for the down-stream regulation of ABA-dependent genes after the reception of the ABA signal (Shinozaki and Yamaguchi-Shinozaki, 1997; 2007). In the present study, we found that the drought-induced ABA accumulation (Fig. 9 in Chapter 4) and the expression of the *NCED* gene (Fig. 8B in Chapter 4) involved in ABA biosynthesis in the root tips were suppressed by Al. Subsequently the drought-induced up-regulation of the transcription factors *bZIP* and *MYB* (Fig. 8C in Chapter 4) and the ABA-dependent genes *SUS*, *PvLEA18*, *KS-DHN* and *LTP* (Fig. 7 in Chapter 4) were also reversed. This series of negative response to additional Al stress may impair the positive role of ABA involved in the maintenance of root elongation under drought, and thus led to greater susceptibility of roots to drought under additional Al stress (Fig. 12 in Chapter 4).

Besides ABA, other phytohormones such as CKs, IAA, SA and JA were also determined in this study (Supplemental Fig. S3 in Chapter 4). It was reported that CKs inhibited root elongation and branching (Skoog and Miller, 1957; Cary et al., 1995; Werner et al., 2001), and that CKs-induced inhibition of root elongation is mediated largely by the production of ethylene (Bertell and Eliasson, 1992; Cary et al., 1995; Růžička et al., 2009). Also, several studies have shown that ABA can suppress ethylene production, and the maintenance of root elongation under water deficit conditions requires the increased levels of ABA to prevent excess ethylene production (Sharp et al., 2000; Spollen et al., 2000; Sharp, 2002; LeNoble et al., 2004). The evidence of a direct effect of ABA on CK is less. However, Jelić and Bogdanović (1988) reported that ABA inhibited the CK-stimulated synthesis of chlorophyll in the light in *Pinus nigra*; Ding et al. (2008) found that ABA could suppress CK activation of cell division in the root cortex of *Medicago truncatula*; Vysotskaya et al. (2009) supposed that ABA could regulate shoot CK concentrations via mediating the enzyme activity of CKX; Takei et al. (2004) observed that ABA treatment highly reduced the CKs biosynthetic genes *CYP735A1* and *CYP735A2* in *Arabidopsis*. Therefore, the potential role of ABA in regulating CKs synthesis can not be ruled out. In the present study, the combined AI and drought stress significantly increased in the root tips of common bean the drought-enhanced concentration of ZR, a biologically active form of CKs (Fig. 10 in Chapter 4) and the expression of the *ACCO* gene (Fig. 6 in Chapter 4) involved in the biosynthesis of ethylene. Therefore, the cross-talk between phytohormones appears to be involved in the enhanced inhibition of root elongation. The AI aggravated drought-induced inhibition of root elongation may partly be due to reduced ABA levels, promoted CK production and subsequently stimulated synthesis of ethylene in the root tips of common bean. The impeded root elongation will restrict the roots to explore water from deeper soil layers and thus reduced drought resistance (Fig. 12 in Chapter 4).

The difference between the two experimental approaches (PEG-simulated drought and dried acidic soil) may result from the possibility to adapt to osmotic stress (PEG-6000) in hydroculture allowing sufficient water uptake to resume root elongation, whereas in dried soil the adaptation fails particularly in presence of AI (Fig. 1, this chapter).

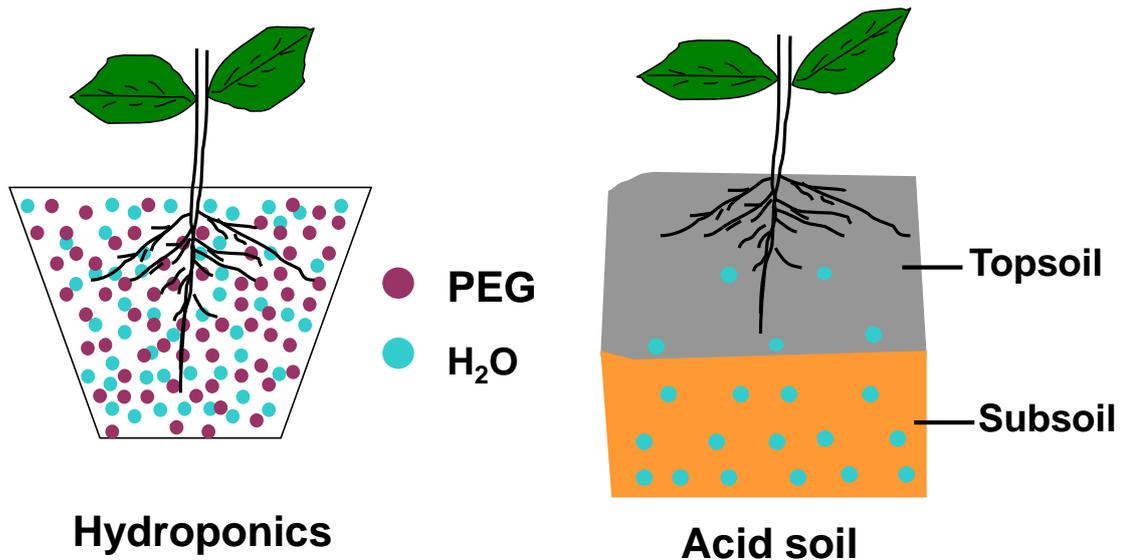

Figure 1 The hypothesized comparison of the two different experimental approaches used to induce combined Al and drought stress (PEG solution and low soil moisture in an acid soil).

In conclusion, PEG-simulated drought (osmotic) stress-inhibited Al accumulation in root apices and thus reduced Al-induced inhibition of root elongation is related to the reduction of CW porosity resulting from PEG 6000-induced dehydration of the root apoplast. The PEG-induced decrease of CW porosity was mediated by genes related to CW assembling and modification such as *XTH*, *BEG* and *HRGP*, and *DHN* may protect the CW from the osmotic stress-induced physical distortion and maintain the capability to restore CW extension. The interaction between Al toxicity and PEG-simulated drought in hydroponics is different from soil conditions. In the soil although drought reduced Al toxicity, the combined Al and drought stress increased the susceptibility of root tips to drought. This aggravated drought-induced inhibition of root elongation in soil results from the disruption of the gene regulatory networks involved in the ABA signal transduction and the ABA signal cross-talk with other phytohormones necessary for maintaining root elongation under drought.

OUTLOOK

The present study clearly showed that in common bean PEG-induced drought (osmotic) stress reduced Al accumulation in the root tips resulting in less inhibition of root elongation. Lower Al accumulation in PEG-treated root tips could be related to the reduction of CW porosity as a result of PEG-induced dehydration of the apoplast. The PEG-induced decrease of CW porosity was mediated by genes related to CW assembling and modification such as *XTH*, *BEG* and *HRGP*, and by dehydrin (DHN) which may protect the CW from the osmotic stress-induced physical breakage and contribute to maintain the capacity for restoration of CW extensibility. The interaction between Al toxicity and PEG-simulated drought was different from in the conditions in an acid, Al toxic soil, where although drought reduced Al toxicity, combined Al and drought stress increased the susceptibility of the root tips to drought indicated by aggravating drought-induced inhibition of root elongation. The Al-induced enhanced drought sensitivity of the root apex resulted from the disruption of the gene regulatory network involved in ABA signal transduction and the ABA signal cross-talk with other phytohormones such as CKs and ethylene, necessary for maintaining root growth under drought.

However, the majority of the conclusions are based on circumstantial evidence, particularly the potential role of the *XTH*, *BEG* and *HRGP* genes in the modification of CW porosity, of the DHN protein in CW protection against physical breakage during PEG-induced osmotic stress, of the role of regulation of ABA-dependent genes and ABA signal transduction and cross-talk in the maintenance of root elongation during drought stress. Therefore, the confirmation of these hypotheses is necessary in the future, to clearly understand the relationship of Al toxicity and drought in common bean and thus breeding for the adaptation to these combined abiotic stresses.

The genes/proteins involved in cell-wall modification

The present study suggest that the PEG-inhibited Al accumulation resulted from the reduction of CW porosity, and that the *XTH*, *BEG* and *HRGP* genes are involved in adjusting CW porosity. However, the exact role and mode of action in modifying CW porosity of the enzymes coded by these genes is still widely unknown. Own additional studies (not reported) may facilitate to better focus future work aiming at better understand the role of CW modification genes in the alteration of wall porosity: (i) The spatial growth analysis of the effect of PEG on roots have demonstrated that the elongation of the root

apical zone (0-2 mm from the root apex) was maintained during PEG-stress, while the elongation in the elongation zone (2-10 mm from the root apex) (Rangel et al., 2007) was strongly inhibited by PEG (Fig. 1, this chapter); (ii) Al binding in the isolated CWs of PEG-pretreated root tips showed that the root apical zone (0-2 mm from the root apex) maintained a comparatively higher level of Al binding in the isolated CWs, whereas PEG strongly decreased the Al binding the CWs in the EZ (2-12 mm from the root apex) (Fig. 2, this chapter); (iii) A kinetic study indicated that the PEG pre-treatment time significantly affected the Al binding in the CWs: the longer duration of the PEG stress the higher the reduction of Al binding (Fig. 3, this chapter). All these physiological results drive us to further investigate the potential involvement of *XTH*, *BEG* and *HRGP* gene in the modification of CW porosity and thus Al accumulation in the root tips at the spatial and temporal levels in the future.

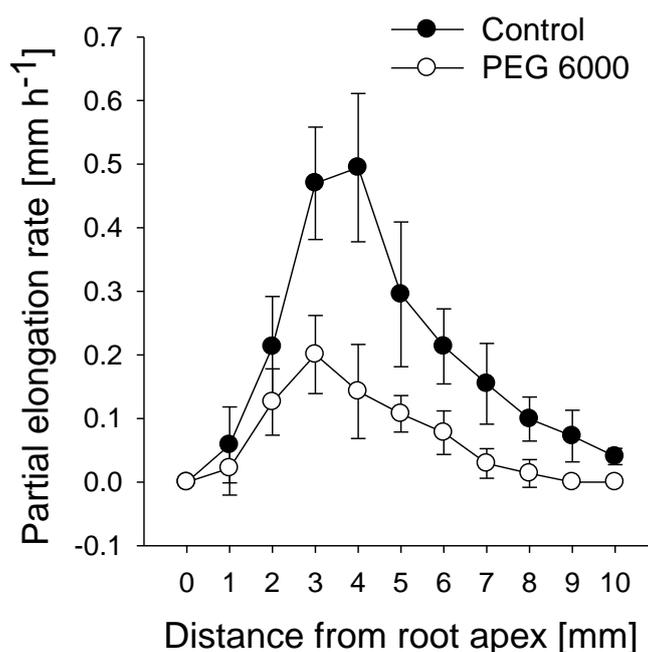

Figure 1 Effect of osmotic stress (-0.60 MPa OP) on the partial-elongation rate of apical 1-cm root segments in common bean genotype VAX 1. Plants were pre-cultured in a simplified nutrient solution containing 5 mM CaCl₂, 1 mM KCl, and 8 μM H₃BO₃ for 48 h for acclimation and pH adaptation, then treated without or with PEG 6000 (150 g L⁻¹) in the simplified nutrient solution for 4 h, pH 4.5. Bars represent means ± SD, n = 9.

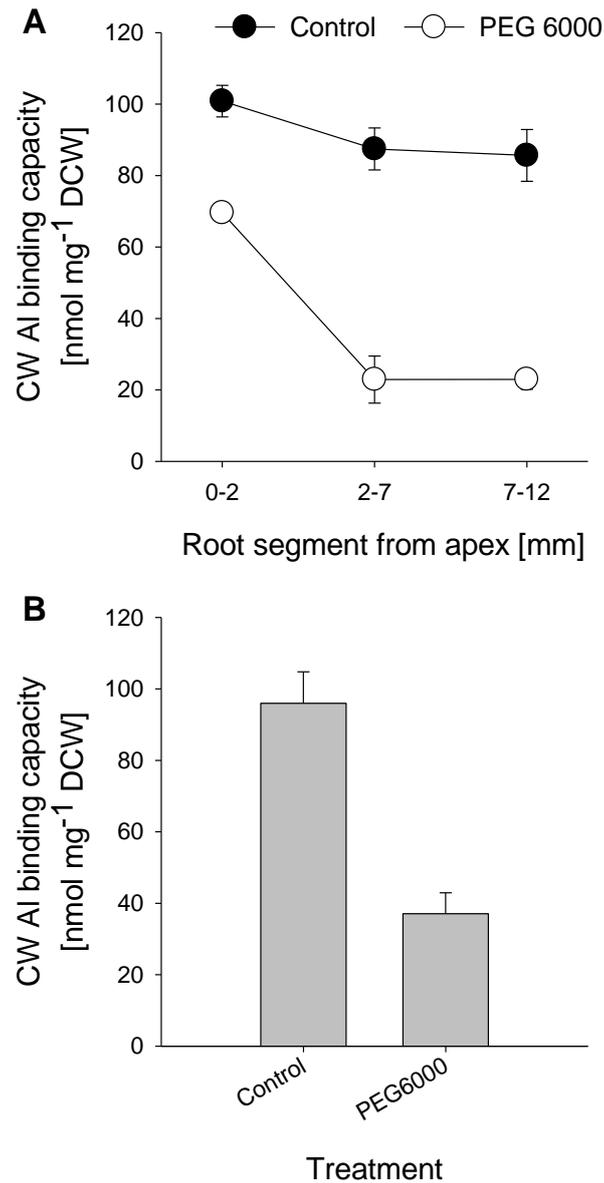

Figure 2 Al³⁺ binding of cell-walls isolated from segments 0-2, 2-7, 7-12 (A), and 0-12 mm (B) from the root apex of the Al-sensitive common bean genotype VAX 1. Plants were pre-treated without or with 150 g L⁻¹ PEG for 24 h in a simplified solution (pH 4.5) containing 5 mM CaCl₂, 1mM KCl and 8 μM H₃BO₃. Then root segments were harvested for each sample and cell-wall material isolated according to Method A described in materials and methods of Chapter 1. Then the isolated cell-wall material (approximately 3 mg) was treated with 1 mL 300 μM Al for 30 min, pH 4.3. Bars represent means ±SD, n = 4.

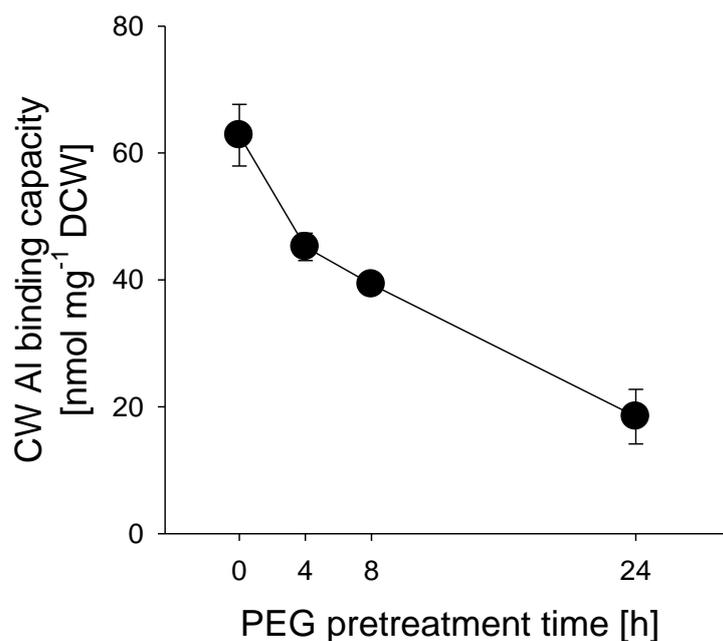

Figure 3 Al³⁺ binding of cell-wall material isolated from of 1-cm root tips of Al-sensitive common bean genotype (VAX 1). Plants were pre-treated with 150 g L⁻¹ PEG for 0, 4, 8 and 24 h in a simplified solution (pH 4.5) containing 5 mM CaCl₂, 1 mM KCl and 8 μM H₃BO₃. Then root tips (1 cm long) were harvested for each sample and cell-wall material isolated according to Method A described in materials and methods of Chapter 1. Then the isolated cell-wall material was treated with 1 mL 300 μM Al for 30 min, pH 4.3. Bars represent means ±SD, n = 4.

Transcriptomic profiling cannot always explain the regulation of biological processes due to protein isoforms or post-translational regulation (Toorchi et al., 2009; Zörb et al., 2010). The combination of proteomics, biochemical assays and transcriptomics may be more successful in clarifying the molecular mechanism of CW modifications leading to alteration of CW porosity. Modification and improvement of the methods of the extraction of CW proteins are necessary in the future, since the methods used in the present study did not yield satisfactory results in the light of our objectives.

Moreover, although the interaction between Al toxicity and drought stress in the root tips of common bean were similar between PEG treatment in hydroponics and low moisture in soil with regard to the expression of genes involved in adjustment of the osmotic potential and CW modification, a more in-depth comparative characterization of common and differential features of stress adaptation is required in the future.

Finally, reverse genetic approaches using gene transformation, gene silencing or mutants are necessary. However, these techniques are still hardly applicable to common bean, presently.

The involvement of ABA crosstalk in the individual and combined drought and aluminium responses

In the present study, the response of the phytohormones ABA, CKs and the gene expression of *ACCO* involved in ethylene production to combined Al and drought stress provide new clues for the further investigation of the potential involvement of ABA-crosstalk. Several studies have clearly shown that ABA can suppress ethylene production, and the maintenance of root elongation under water deficit conditions requires increased ABA levels to prevent excess ethylene production (Sharp et al., 2000; Spollen et al., 2000; Sharp, 2002; LeNoble et al., 2004). Furthermore, ethylene can mediate the CK-induced inhibition of root elongation (Bertell and Eliasson, 1992; Cary et al., 1995; Růžička et al., 2009) by the overexpression or mutation of genes involved in the phytohormone biosynthesis and signal transduction pathways. Therefore, the information provided by the present study may facilitate the design of future studies aiming at clarifying the mechanisms involved in the Al and drought interaction.

Opportunities in breeding for adaptation to combined Al toxicity and drought

Using different bean species, Butare et al. (2011) found that Al partially ameliorated the negative effects of water stress in *Phaseolus coccineus* genotypes, strongly in contrast to *Phaseolus acutifolius* and the Mesoamerican common bean genotypes (such as VAX 1, the genotype used in this study) where combined stress led to a more severe inhibition of root development strongly supporting our present study in soil. Therefore, it appears promising to use interspecific crosses with *Phaseolus coccineus* to improve combined drought tolerance and Al resistance of common bean.

SUPPLEMENTAL DATA

The Interaction between Aluminium Toxicity and Drought Stress in Common Bean (*Phaseolus vulgaris* L.): Physiological and Molecular Aspects

SUPPLEMENTAL DATA FOR CHAPTER 1

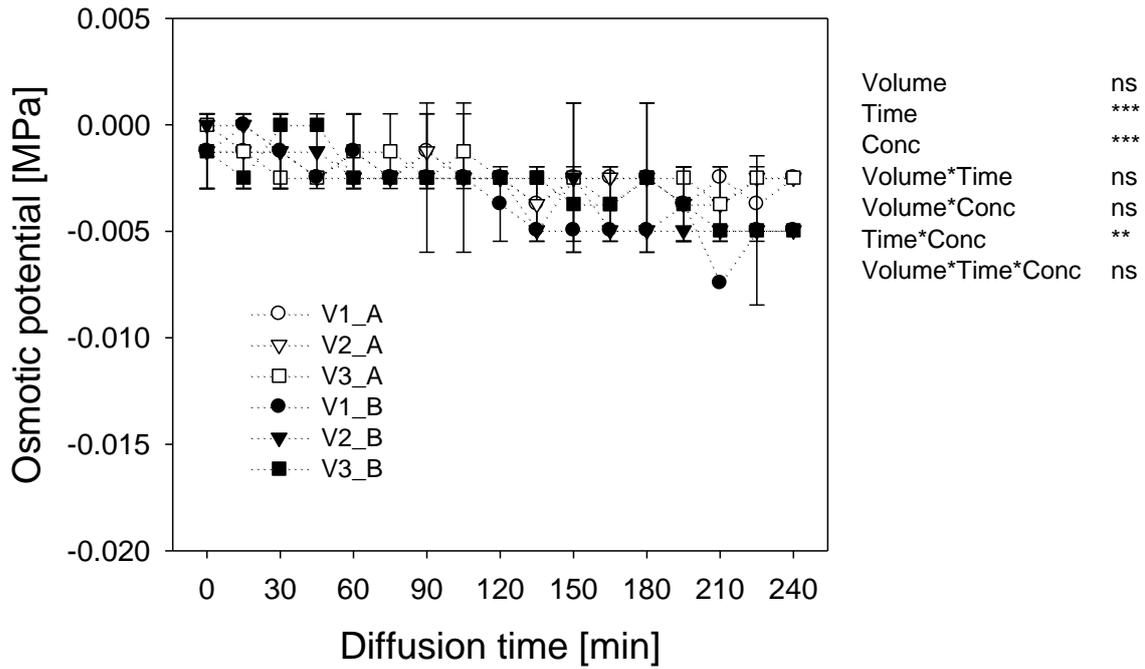

Alteration of cell-wall porosity is involved in osmotic stress-induced enhancement of aluminium resistance in common bean (*Phaseolus vulgaris* L.)

Zhong-Bao Yang¹, Dejene Eticha¹, Idupulapati Madhusudana Rao², Walter Johannes Horst¹

² International Center for Tropical Agriculture (CIAT), AA 6713, Cali, Colombia

Journal Experimental Botany (2010) 61: 3245-3258

Supplemental Figure S1 Diffusion of low molecular weight PEG through DMT. PEG 6000 was incubated in DMT in 1.0 (V1), 1.5 (V2) or 2.0 (V3) L distilled water. A = original solution, B = 10 x concentrated solution. For the ANOVA, **, *** denote significant differences at $P < 0.01$, $P < 0.001$, respectively; ns = not significant (F test).

Supplemental Figure S2 Freeze-fracture scanning electron micrographs of root-tip cross-sections (1-5 mm from the root apex) of common bean genotype VAX 1 grown for 4 h in the presence of different molecular weight PEG. Upper row show root cross-section segments from the epidermis (Ep) through the cortex (Co) to the central cylinder (CCy), lower row pictures show the epidermis and one outer cortical cell layer (OC). Arrows indicate the presence (A, B, D, E.) or absence (C, F) of intercellular spaces between the epidermis and the outer cortical cell layer. A, D: control; B, E: PEG 1000; C, F: PEG 6000. Scale bars correspond to 40 μ m in A, B and C, 10 μ m in D, E and F.

SUPPLEMENTAL DATA FOR CHAPTER 2

SUPPLEMENTAL DATA FOR CHAPTER 3**Proteomic analysis of polyethylene glycol-induced osmotic stress in root tips of common bean (*Phaseolus vulgaris* L.)**

Zhong-Bao Yang¹, Dejene Eticha¹, Hendrik Führs¹, Sébastien Gallien², Dimitri Heintz³, Alain Van Dorsselaer², Idupulapati Madhusudana Rao⁴, Walter Johannes Horst¹

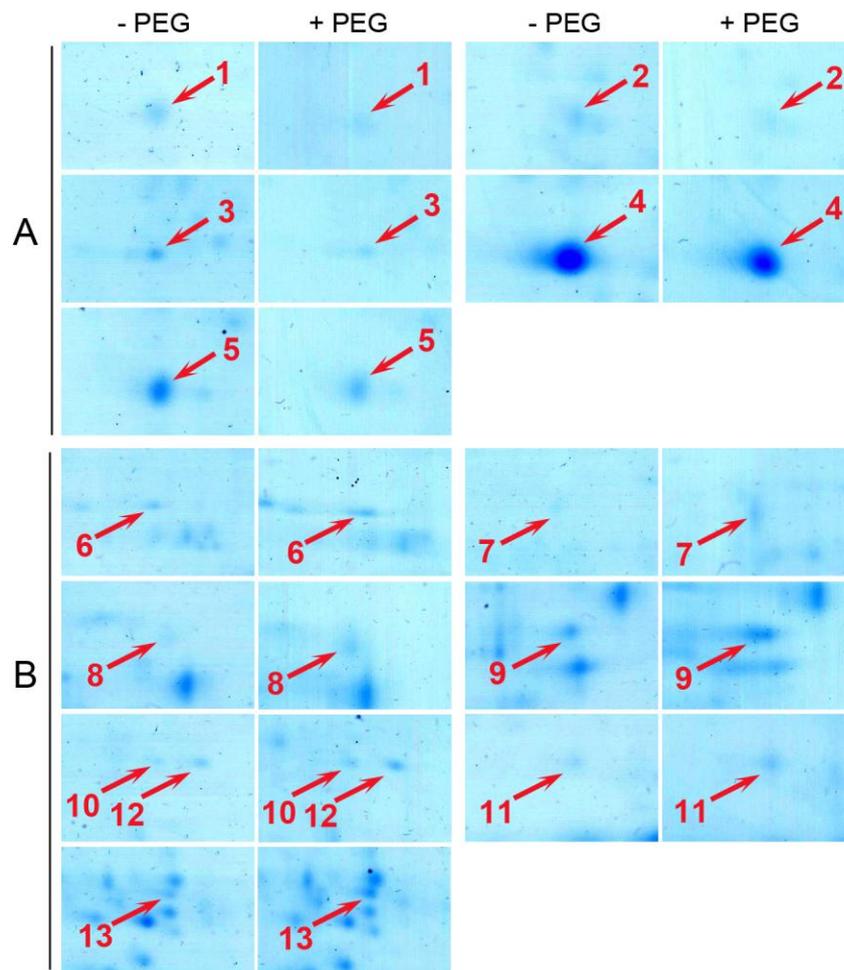

¹ Institute of Plant Nutrition, Leibniz Universität Hannover, Herrenhaeuser Str. 2, D-30419 Hannover, Germany

² Laboratoire de Spectrométrie de Masse Bio-organique, IPHC-DSA, Université de Strasbourg, CNRS, UMR7178, 25 rue Becquerel, 67087 Strasbourg, France

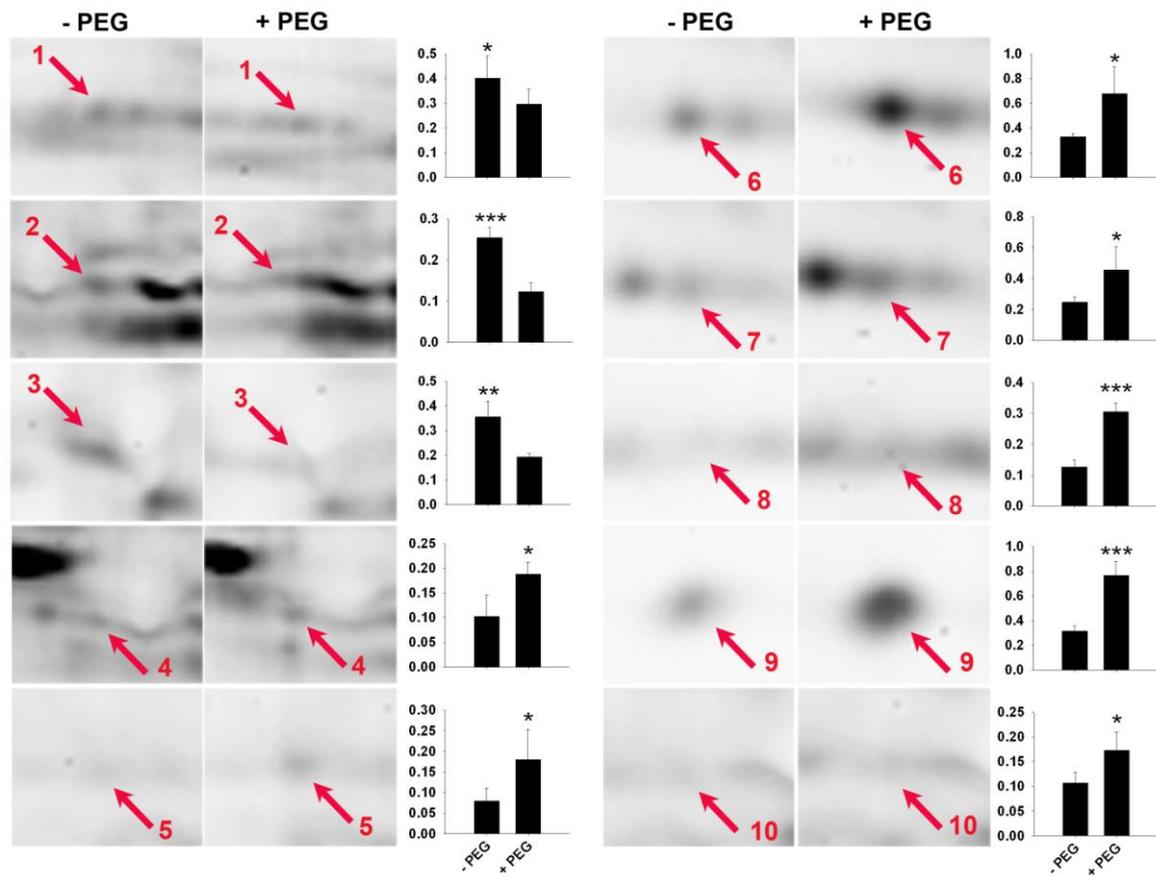

³ Institut de Biologie Moléculaire des Plantes (IBMP), 28 rue Goethe, CNRS-UPR2357, Université de Strasbourg, 67083 Strasbourg, France

⁴ International Center for Tropical Agriculture (CIAT), AA 6713, Cali, Colombia

(To be submitted)

Supplementary Figure S1 Close-ups of the decreased (A) and increased (B) apoplastic proteins in response to PEG in the root tips of common bean genotype VAX 1. The intact Coomassie-stained 2D IEF/SDS-PAGE gels of the apoplastic proteins were shown in Fig. 5.

Supplementary Figure S2 Close-ups of the decreased and increased phosphoproteins in response to PEG in the root tips of common bean genotype VAX 1, and the corresponding changes of relative volume in these ten phosphoproteins were presented. The intact Pro-Q DPS-stained 2D IEF/SDS-PAGE gels of the total phosphoproteins were shown in Fig. 6A. The symbol *, ** and *** denote significant differences at $P < 0.05$, 0.01 and 0.001, respectively.

SUPPLEMENTAL DATA FOR CHAPTER 4

Physiological and molecular analysis of the interaction between aluminum toxicity and drought stress in common bean (*Phaseolus vulgaris* L.)

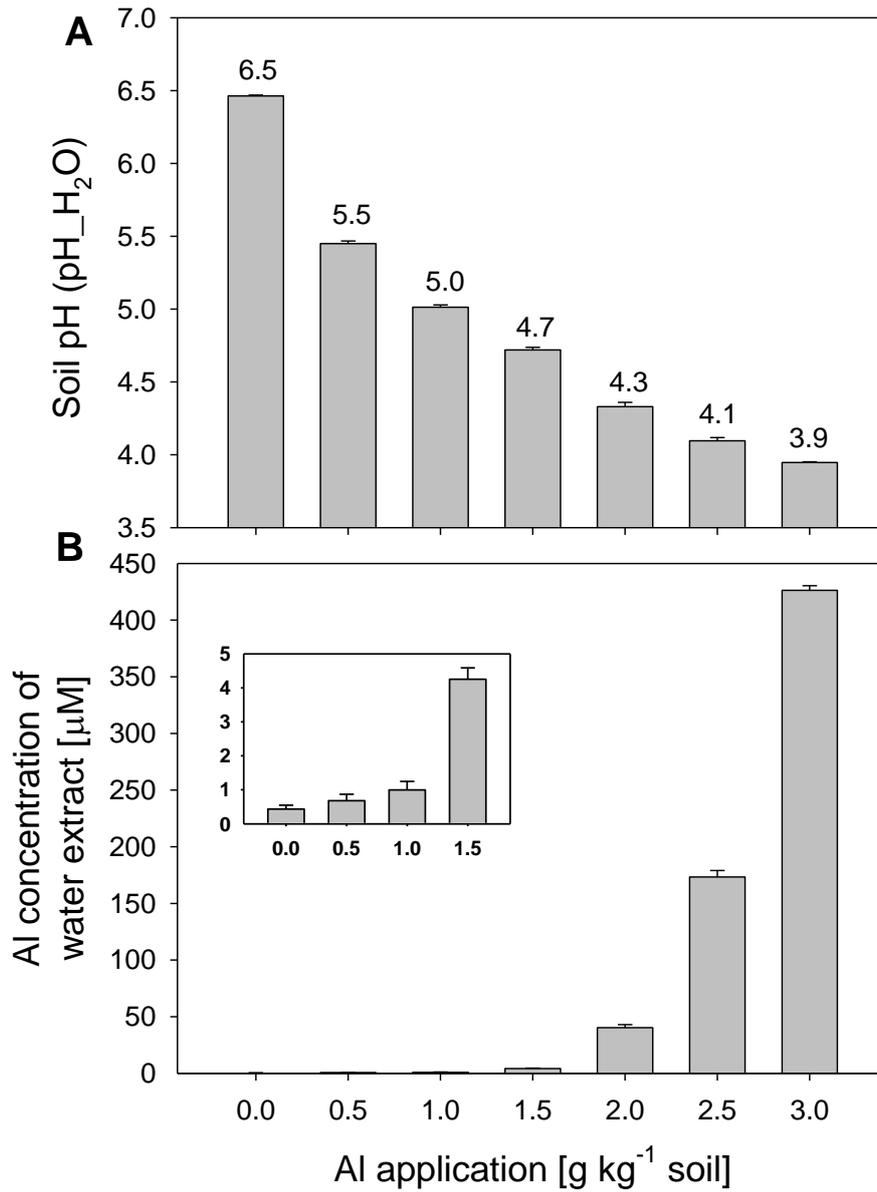

Zhong-Bao Yang¹, Dejene Eticha¹, Alfonso Albacete², Idupulapati
Madhusudana Rao³, Thomas Roitsch², Walter Johannes Horst¹

¹ Institute of Plant Nutrition, Leibniz Universität Hannover, Herrenhaeuser Str. 2, D-30419
Hannover, Germany

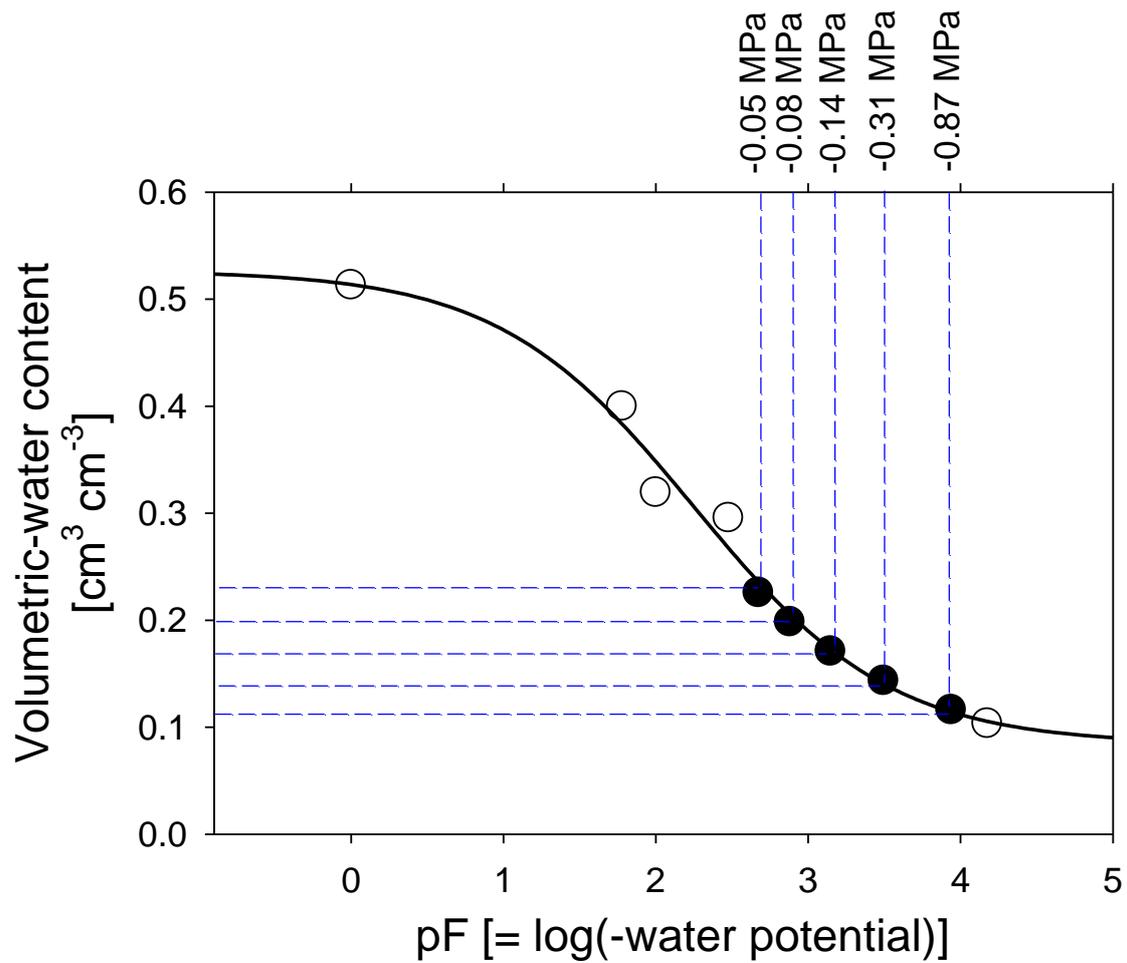

² Institute of Plant Science, Universität Graz, Schubertstrasse 51, A-8010 Graz, Austria

³ International Center for Tropical Agriculture (CIAT), AA 6713, Cali, Colombia

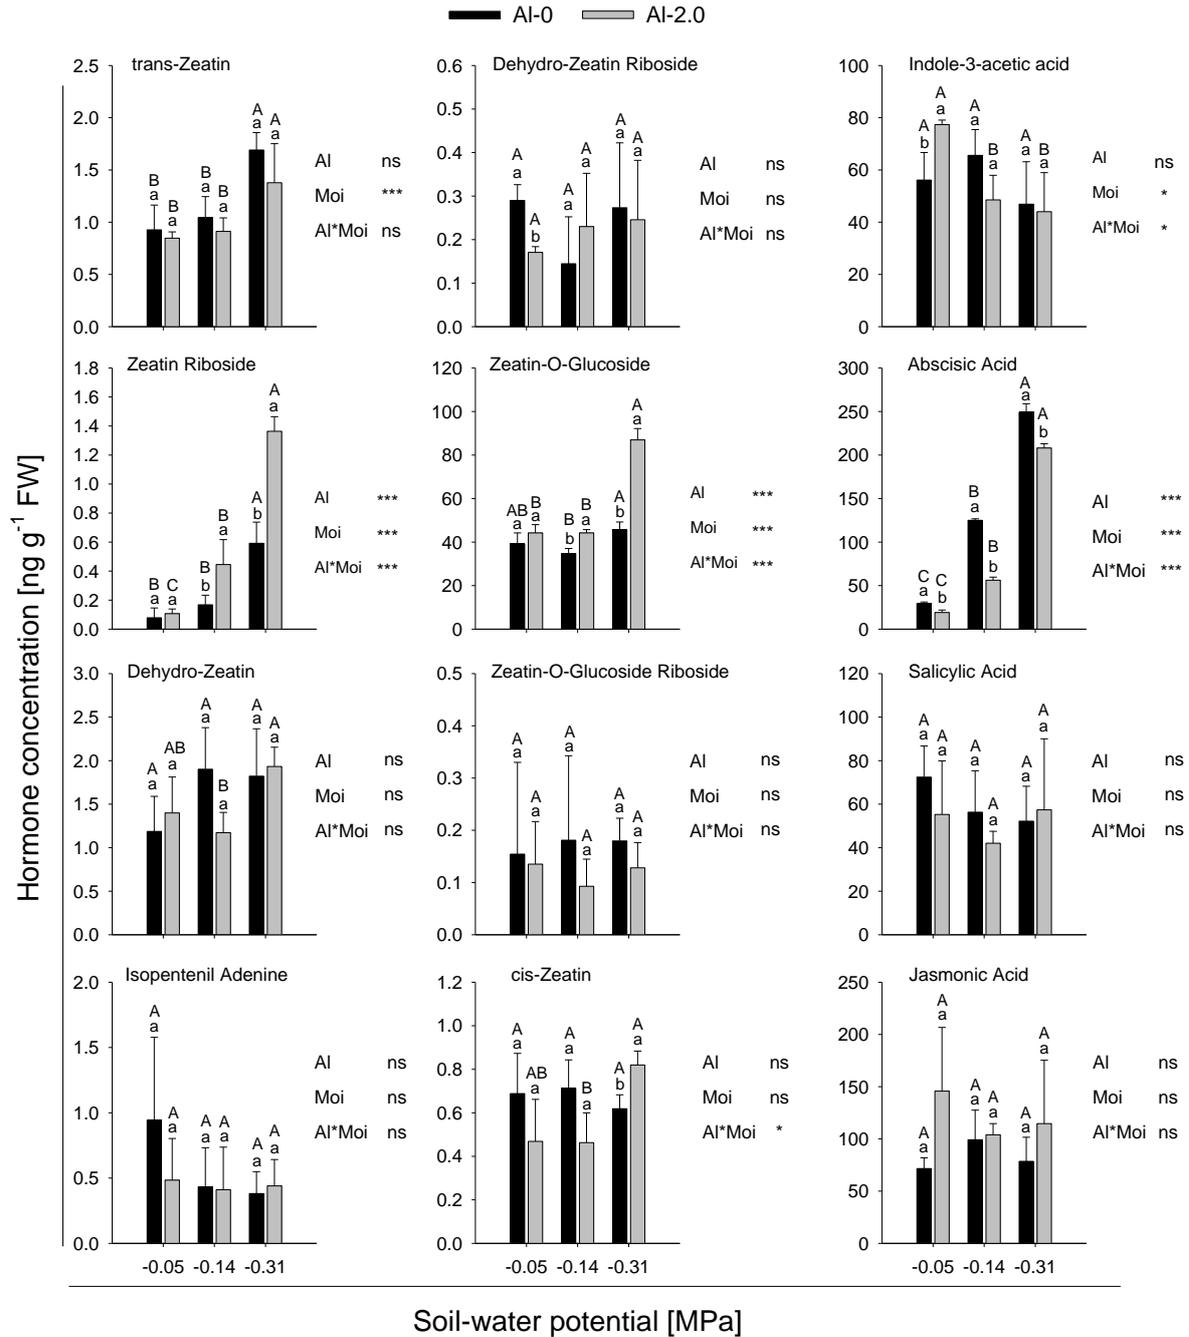

(To be submitted)

Supplemental Figure S1 Soil pH ($\text{pH}_{\text{H}_2\text{O}}$) (A) and the corresponding Al concentrations in the water extracts (B) at different levels of Al application (0 to 3.0 g kg^{-1} soil). 10 mg air dried soil was incubated in 20 ml distilled water ($\text{pH}_{\text{H}_2\text{O}}$), and shaken for 1 h, then the soil pH and Al concentrations were determined. In B, the inserted graph shows the downscaled data for the Al supplies from 0 to 1.5 g kg^{-1} soil.

Supplemental Figure S2 The soil water retention curve of an Oxisol from the Llanos region of Colombia. The filled dots indicate the soil-moisture treatments used in the present study; the corresponding soil-water potentials in MPa are presented on the top of the graph.

Supplemental Figure S3 Phytohormone concentrations in the 1-cm root tips of the common bean genotype VAX 1 as affected by soil moisture and Al supply (g kg^{-1} soil). Two-day-old seedlings were grown in soil for 24 h. Bars represent means \pm SD, $n = 3$. Means with different small and capital letters are significantly different at $P < 0.05$ (Tukey test) for the comparison of Al treatments within soil moisture and comparison of soil-moisture treatments within Al treatments, respectively. For the ANOVA, *, *** denote significant differences at $P < 0.05$, $P < 0.001$, respectively. ns = not significant.

Supplemental Table S1 List of genes and specific primer pairs used for quantitative gene expression analysis.

Candidate genes	Primer pairs (5'→3')*		Amplicon size (bp)	TC/GB Acc. No.
<i>P5CS</i> (VuP5CS protein)	(+) GACAGTGCTGCTGTTTCCA	(-) AAACCCTCTACTCCCACAGGA	128	TC14708
<i>SUS</i> (Sucrose synthase 2)	(+) GCATGGCCTCATGAAAGAGT	(-) GAAAGCAGGCTGAACGAAAG	133	TC11609

* (+) and (-) indicate forward and reverse primers, respectively.

CURRICULUM VITAE

Personal Data

Name: Zhongbao Yang
Date of Birth: November 28, 1979
Place of birth: Tancheng, Shandong province, PR China
Sex / Marital Status: Male / Married
Nationality: PR China
E-mail: zhongbao@pflern.uni-hannover.de

Education

2007 - 2011 Ph.D. Gottfried Wilhelm Leibniz University of Hannover, Faculty of Natural Science, Institute of Plant Nutrition, Hannover, Germany.
2004 - 2007 Master of Agriculture, Jilin University, College of Plant Science, Changchun, PR China.
2000 - 2004 Bachelor of Agriculture, Laiyang Agricultural College, Department of Horticulture, Laiyang, PR China

Main Research

- Adaptation of plants to adverse soil conditions (aluminum toxicity, drought stress, manganese toxicity).

Awards

- Scholarship award from China Scholarship Council (CSC)
- Poster awards (2nd)

Yang ZB, Eticha D, Rao IM, Horst WJ (2008) The interaction between aluminium toxicity and drought stress in common bean (*Phaseolus vulgaris* L.). Abstract and Poster in Annual Conference of the German Society of Plant Nutrition. pp 39.

Erklärung zur Dissertation

gemäß §6(1) der Promotionsordnung der Naturwissenschaftlichen Fakultät der Gottfried Wilhelm Leibniz Universität Hannover

für die Promotion zum Dr. rer. nat.

Hierdurch erkläre ich, dass ich meine Dissertation mit dem Titel

The Interaction between Aluminium Toxicity and Drought Stress in Common Bean (*Phaseolus vulgaris* L.). Physiological and Molecular Aspects

selbständig verfasst und die benutzten Hilfsmittel und Quellen sowie gegebenenfalls die zu Hilfeleistungen herangezogenen Institutionen vollständig angegeben habe.

Die Dissertation wurde nicht schon als Masterarbeit, Diplomarbeit oder andere Prüfungsarbeit verwendet.

ACKNOWLEDGEMENTS

First of all, I would like to express my heartfelt gratitude to **Prof. Dr. Walter J. Horst**, for giving me the opportunity to study in the Institute of Plant Nutrition and specifically to work on an interesting project in such a dynamic subject. His inspiring enthusiasm, tireless supervision, diligent guidance, kind and manifold supports through all stages of my study have helped me to successfully accomplish this work.

Special thanks go to **Dr. Dejene Eticha**, a very kind and friendly person, from whom I learned most of the methods used for my study. Whenever I had difficulties during my study, he has always helped me with full engagement and great patience. His valuable suggestions during the whole study and constructive comments during manuscript preparation substantially improved the whole work.

Many thanks to **Dr. Hendrik Führs, Dr. Benjamin Klug, Dr. Andrés F. Rangel, Dr. Yunxia Wang**, PhD students **Katharina Bollig, Fabian Köslin-Findeklee, Alexander Fleck**, for their valuable suggestions and great help during the study. Thanks to **André Specht, Anne Herwig, Iris Wienkemeier, Hartmut Wieland** for their unreserved technical support. Thanks to **Mrs. Ingrid Dusy** who has taken care of the social and administrative aspect that helped me not only to work successfully in the laboratory but also to enjoy the pleasant time in Germany. I also thank all colleagues and co-workers of the Institute of Plant Nutrition for sharing good time together during the last four years.

I extend my thanks to all cooperators of my study project particularly, **Dr. I.M. Rao and Dr. S. Beebe** from CIAT, **Prof. Dr. P. Baur** and **Mr. S. Treitscheid** from Bayer CropScience, **Dr. B. Rotter** from GenXPro GmbH, **Dr. D. Heintz, S. Gallien** and **A.V. Dorsselaer** from Université de Strasbourg, **Pro. Dr. T. Roitsch, Dr. A. Albacete** from Universität Graz, **Prof. Dr. J. Bachmann, Dr. M. Volkmann** and **Dr. S.K. Woche** from Leibniz Universität Hannover.

I thank the **China Scholarship Council (CSC)**, for providing the scholarship and supporting during the four years of my study time in Germany. The financial support of my study project which was donated by **BMZ/GTZ** as a restricted core project (No. 05.7860.9-001.00) granted to the International Center for Tropical Agriculture (CIAT) is highly acknowledged.

Finally, I would like to thank my father, mother and the family of my sister for giving me a constant support. Last but not least, my special thanks and lots of love goes to my wife, **Chunping Zhang**, for her love, patience, understanding, constant support and encouragement during the whole study period.
