## Zusammenfassung

Die Samenentwicklung von Pflanzen wird durch den einzigartigen Mechanismus der doppelten Befruchtung initiiert. Die daraus entstehenden Samengewebe, Endosperm und Embryo, durchlaufen während ihrer Entwicklung charakteristische Stadien von der Gewebedifferenzierung bis hin zur Einlagerung von Speicherstoffen. Dieser Prozess ist durch vielfältige Veränderungen auf zellulärer und molekularer Ebene gekennzeichnet. In der vorliegenden Arbeit wurden die physiologischen und molekularen Mechanismen während der Samenentwicklung und die Rolle der verschiedenen Samengewebe untersucht (Kapitel 2.1). Im Rahmen dieser Untersuchung wurde eine proteomische Strategie entwickelt, welche (i) die Etablierung einer Endosperm-Referenzkarte, (ii) die Charakterisierung der Endosperm-entwicklung und (iii) den Vergleich des Endosperm- und Embryoproteoms umfasste. In dieser ersten Untersuchung zur Endosperm-entwicklung von *Brassica napus* konnte gezeigt werden, dass das Endosperm neben seiner Funktion als Nährstoffspeicher ein eigenständiges und stoffwechselaktives Gewebe innerhalb des Samens repräsentiert. Die Identifizierung spezifischer Stoffwechselwege und regulatorischer Elemente lieferte einen Hinweis auf molekulare Interaktionen zwischen dem Endosperm und dem Embryo. Der etablierte proteomische Versuchsaufbau eignet sich für die Analyse von Samen unabhängig von der Spezies und lieferte neue Erkenntnisse zur Endospermfunktion in *Cyclamen persicum* (Kapitel 2.3) und zu spezifischen Eigenschaften zygotischer und somatischer Embryonen von *Theobroma cacao* (Kapitel 2.4). Sobald die Differenzierung der Samengewebe abgeschlossen ist, beginnt die massive Einlagerung von Speicherstoffen wie Lipiden und Proteinen. Da die Akkumulierung von Speicherproteinen von zentraler Bedeutung für die Keimung ist, wurde die native Struktur des Cruciferins aus *B. napus* Samen charakterisiert (Kapitel 2.2). Der Cruciferin-Komplex ist durch eine oktamere, fassförmige Struktur gekennzeichnet. Diese Struktur ermöglicht eine effiziente Speicherung von Aminosäuren auf kleinstem Raum. Sowohl Entwicklungsprozesse als auch die Speicherstoffsynthese erfordern große Mengen an Reduktionsäquivalenten und Energie. Es wird vermutet, dass Samen alternative Möglichkeiten zur Energiebereitstellung, wie den Abbau von Aminosäuren, besitzen. Erste detaillierte Analysen zur Funktion einer mitochondrialen Schwefeldioxygenase ETHE1 unterstützen die Hypothese, dass der Aminosäurestoffwechsel in Samen eine zentrale Rolle spielt und an der Bereitstellung von Stickstoff und Energie beteiligt ist (Kapitel 2.5, Kapitel 2.6). Die in dieser Arbeit präsentierten neuen Ergebnisse zur Biologie der Samenentwicklung, insbesondere zur Speicherstoffsynthese und zum Aminosäurestoffwechsel, könnten künftig genutzt werden, um die Samenqualität und den Ertrag von Nutzpflanzen zu verbessern.

**Schlagworte:** Proteomik, Samen, Endosperm, Embryo, Speicherstoffeinlagerung

## Abstract

Plant seed development starts with the unique event of double fertilization. The resulting seed tissues endosperm and embryo undergo characteristic developmental sequences with dramatic changes on cellular and molecular level spreading from tissue differentiation and growth to storage deposition during seed filling. In the course of this thesis special emphasis was placed on the physiological and molecular characterization of developmental mechanisms and their impact on different seed compartments ([chapter 2.1](#)). For this purpose a proteomic strategy including (i) establishment of an endosperm proteome reference map, (ii) characterization of endosperm development and (iii) comparison of endosperm and embryo proteomes was designed. This first study of endosperm development in *Brassica napus* highlighted that beside its nutritive function the endosperm represents a self-competent and metabolically active tissue. Furthermore, it has been shown that several pathways and regulatory elements govern the biochemical interplay between the embryo and the endosperm. The established proteomic workflow can be applied to seeds of different species. Here, it revealed new insights into endosperm function of *Cyclamen persicum* ([chapter 2.3](#)) and characteristics of zygotic and somatic embryos of *Theobroma cacao* ([chapter 2.4](#)). Once the tissue differentiation is terminated storage compounds such as lipids and proteins are massively accumulated in the embryo of dicotyledonous species such as oilseeds. Since efficient protein storage is essential for germination success the native structure of *B. napus* cruciferin was characterized ([chapter 2.2](#)). It revealed insights into structure and packing of seed storage proteins. The cruciferin complex has an octameric barrel-like structure optimized for maximum amino acid storage capacity with minimal space requirements. Both, seed development and storage activity require high amounts of energy and reduction equivalents. It is proposed that in seeds alternative routes like amino acid degradation contribute to energy provision for efficient energy metabolism. First detailed investigations on the function of the mitochondrial sulfur dioxygenase ETHE1 in seeds support the hypothesis that amino acid metabolism is highly important in seeds and may serve in nitrogen and energy provision during seed development ([chapter 2.5](#), [chapter 2.6](#)). The novel insights into seed biology presented in this thesis, in particular for storage product synthesis and amino acid metabolism, are potential targets for strategies aiming to improving seed quality and yield of crops in the future.

TAG	triacylglycerol
TCA	tricarboxylic acid
t-SIM	targeted-selected ion monitoring
VLCFA	very long chain fatty acid

## Chapter 1: Seed biology and plant proteomics

Why studying seed biology is of great importance? Seeds contain the entire repertoire of compounds needed for plant germination. They adapt to multitude (sometimes adverse) environmental conditions and plants developed unique mechanisms for their dispersal. Most of the seeds contain large and specific quantities of storage compounds which are important and sometimes essential components of animal and human diets. Thus, the biological and economic importance of seeds is evident. This chapter provides insights into processes involved in seed development and a global overview of the theoretical background of the thesis. In addition, recent findings in the field of seed biology and plant proteomics are presented and discussed.

### 1.1 Seed development of dicotyledons: An overview

Seed development starts with the unique event of double fertilization in which one sperm cell fuses with the egg cell to form the embryo while a second sperm cell unites with the central cell resulting in the triploid endosperm. The seed compartments undergo unique developmental changes underpinned by dramatic changes on cellular and molecular level (Figure 1). These differentiations are controlled by maternal tissues first and by filial organs in the later stages.

**Figure 1: Embryo and endosperm development in the model plant *Arabidopsis thaliana*.** Seeds were harvested from 1 to 9 DAP (a) and subsequently analysed by light microscopy (b). The endosperm and embryo follow distinct differentiation processes (c). **DAP**, days after pollination.

### 1.1.1 Embryogenesis

Embryogenesis comprises a stepwise differentiation of the fertilized zygote including cell division, cell elongation, greening and photosynthetic activity as well as accumulation of seed storage products. Overall, two distinct phases can be defined: (i) morphogenesis and (ii) maturation (Goldberg et al. 1994). The initiation of embryo formation and development is controlled by pronounced gene activity (Rodoeva and Weijers 2014). After fertilization of the egg cell a pro-embryo containing an apical and a basal cell merges defining the polarity of the embryo. The apical cell gives rise to the embryo, while the basal cell forms the suspensor, a connective structure between filial and maternal tissues. At later stages the suspensor degenerates and the metabolic connection to the mother plant is interrupted (Kawashima and Goldberg 2010). Through further cell divisions, elongation and differentiation processes the embryo acquires the building plan of the plant (De Smet et al. 2010, Lau et al. 2012). The morphogenetic processes during embryogenesis depend on regulatory networks, particularly on cell cycle regulation which ensures the formation of different cell types and tissues (Dante et al. 2014, Wendrich and Weijers 2013). During maturation the synthesis and massive accumulation of storage products is prominent. At a very late maturation stage, the embryos metabolic activity is terminated and the seed becomes tolerant to desiccation. The previously accumulated storage products can be degraded during germination to provide nutrients to the growing seedling, before photosynthetic activity is established (Baud et al. 2002).

### 1.1.2 Endosperm development

The endosperm is essential for embryo development during seed formation in plants. It embeds the embryo and is itself surrounded by the seed coat. In dicotyledonous species, e.g. *A. thaliana* and *B. napus*, the endosperm is of transient nature and only the aleurone layer remains until seed maturity (Novack et al. 2010). The endosperm development is characterized by a stepwise differentiation including transition from a syncytial to a cellular phase (Olsen 2004, Berger 2003, Brown et al. 2003, Brown et al. 1999). The syncytium is produced by several cycles of mitosis of the fertilized central cell in the absence of cytokinesis, thus leading to a multi nuclear cell (Olsen 2004). In the course of seed development the endosperm is divided into three mitotic domains: (1) the micropylar, (2) the peripheral and (3) the chalazal region in which nuclei divide simultaneously (Boisnard-Lorig et al. 2001). The syncytium becomes cellularized by the formation of radial microtubule systems originating from the micropylar region (Olsen 2004, Sørensen 2002, Brown et al.

1999). The process of cellularization has a decisive impact on embryo development (Hehenberger et al. 2012) and conducts the initiation of embryo growth (Brown et al. 1999). When endosperm development is terminated, programmed cell death leads to endosperm cell degradation which is probably controlled by ethylene and interactions between embryo and endosperm (Berger et al. 2006, Young and Gallie 2000, Berger 1999). The remaining aleuronic layer holds key functions in the deposition of storage compounds and enzymes, as well as desiccation and germination of seeds (Yan et al. 2015, Holdsworth et al. 2008, Bethke et al. 2007, Penfield et al. 2004).

### 1.1.3 Physiological and molecular determinants controlling seed development

The interplay of different seed compartments on various levels is crucial for coordinated seed development. However, regulatory mechanisms and communication between compartments are not yet fully elucidated. Recent studies provided further insights into signal transduction and transport processes.

In dicotyledonous seeds the endosperm develops first, while embryo development is paused. Due to its location the endosperm is able to coordinate maternal and filial contributions (Novack et al. 2010). Studies of mutants carrying endosperm specific defects have given insights into development and function of this compartment. Many mutations of endosperm related genes affect functions in cell differentiation, cellularization and cell growth (Hehenberger et al. 2012, Lu et al. 2012, Cavel et al. 2011, Lee et al. 2012, Sabelli and Larkins 2009, Ohto et al. 2005, Garcia 2003). Seed growth is directly linked to seed yield (Adamski et al. 2009) and understanding the mechanisms controlling the seed size therefore is essential (Orozco-Arroyo et al. 2015, Boissard-Lorig et al. 2001). The seed coat acts as a physical barrier restricting embryo expansion, particularly that of the cotyledons (Fang et al. 2012, Haughn and Chaudhury 2005). Elements influencing endosperm development comprise cell cycle control, genomic imprinting, hormones and environmental conditions (Bauer and Fischer 2011, Wolff et al. 2011, Huh et al. 2007, Berger 2004, Gehring et al. 2004). The endosperm has distinct functional regions to coordinate developmental processes. For cereals it is known that the endosperm forms transfer cells (ETC) and embryo surrounding region (ESR) which mediate nutrient shuffling to the embryo and might be involved in signaling processes (Thiel 2014, Olsen 2004). So far, ESRs have not been characterized in dicotyledons, but it is very likely that also species with a transient endosperm are building

metabolic active regions supporting embryo growth. However, it remains to be investigated if putative dicotyledonous ESR is functionally equivalent to the one identified in cereals. The general and specific metabolic functions of the endosperm are just beginning to emerge (Lafon-Placette and Köhler 2014, Belmonte et al. 2013, Huang et al. 2009). A recent analysis has shown that the molecular architecture of *B. napus* endosperm comprises the entire set of central metabolic pathways (Lorenz et al. 2014, chapter 2.1). Besides its nutritive function, the endosperm fulfils key functions in metabolism and signaling. Its enzymatic machinery turns the endosperm into a self-sustaining and metabolically active tissue, which receives major assimilates from the mother plant, but which is also able to produce metabolic intermediates by itself. Shifts in metabolism are reflecting the dramatic changes on cellular level. It is particularly unknown to which extent endosperm metabolism can modulate the incoming stream of assimilates thereby shaping differentiation, growth and storage compound formation of the embryo. Belmonte et al. (2013) presented developmental profiles of *A. thaliana* gene activity and characterized functional differentiation of subregions from fertilization to maturation. Coexpression analyses of identified genes suggest that processes defining seed size and regulating storage product accumulation are coordinated across several regions within the seed. Investigations indicate a high number of transcription factors and regulatory components in seeds (Lorenz et al. 2014, Le et al. 2010), but only a minor number of transcription factors have been characterized so far. It appears very likely that their involvement in various signaling cascades makes a fundamental contribution to programming and regulation of seed development.

Seed development as a whole not only depends on the progress of each of the individual compartments (seed coat, embryo and endosperm), it also relies on the cross-talk between all compartments ensuring adjustment of the developmental processes in response to developmental cues. The endosperm is a connective tissue within the seed and provides the environment meeting the needs of the growing embryo. Communication routes in plant cells can either run through the symplast or the apoplast. Apoplastic transport is supported by membrane-localized transporters, while symplastic transport involves plasmodesmata. These micro channels are the connecting elements of cytoplasm and endoplasmic reticulum (ER) of neighboring cells and allow the exchange of hormones, metabolites, RNAs and small proteins (Xu and Jackson 2010). It is proposed that communication routes change several times during development (Kim et al. 2005, Lee and Yeung 2010). In seeds secreted peptides are highly abundant in specific cells and compartments. Recent findings suggest that their specific

accumulation might regulate signal cascades (Ingram and Gutierrez-Marcos 2015). For example, a peptide derived from the *Arabidopsis* CLAVATA3/embryo surrounding region-related 8 (CLE8) influences embryo cell division, endosperm proliferation and the timing of endosperm differentiation (Fiume et al. 2011). A different peptide (KISS OF DEATH, KOD) expressed in embryos is involved in the degradation of the suspensor cell (Blanvillain et al. 2011). It is suggested that peptides might be utilized to control developmental processes in plants in general (Costa et al. 2014), although their exact role in regulatory processes have not yet been fully elucidated. Furthermore, a tight redox control in the endosperm is of highest significance to ensure non-oxidizing conditions. Such conditions were recently proposed to be of key importance for germ cell fate and sexual reproduction (Kelliher and Walbot 2012). In vegetative tissues redox signals derived by photosynthetic activity regulate Calvin cycle, ATP generation, NADPH export, starch metabolism, carbon fixation, lipid synthesis and amino acid synthesis (Considine and Foyer 2014). The components of the redox-signaling pathway mainly respond to physiological and environmental inputs. The redox status in seeds is expected to be regulated using the glutathione system (Cairns et al. 2006).

Remarkable progress is currently made in understanding the interactions of different seed compartments and signaling processes, but many gaps are yet to be filled. Future challenges include the integration of different research fields such as microscopic analysis, metabolomics, transcriptomics and proteomics. Such a system biology approach is a promising avenue to unravel communication systems and to identify checkpoints of developmental control in seeds.

## 1.2 Seed proteomics: Methods and applications

The term proteome was introduced in 1996 by [Wilkins et al.](#) and defined as “the total protein complement of a genome”. However, a proteome is highly complex with respect to the chemical properties and the variable range of its constituents. In addition the proteome is dynamic and therefore its composition depends on several factors. Proteins are the functional and structural units within a cell and continually undergo changes due to biosynthesis and degradation, metabolic activity, interaction with other proteins to form complexes and post translational modifications. Protein function itself is regulated by external and internal cues. Thus, the investigated proteome reflects the current biological state and can be defined as the molecular phenotype of any given biological sample. Proteomic analyses are suitable for whole organisms, organs, specific tissues, cell types or organelles. Among all “omics”-techniques, proteomics represents a key technology to investigate dynamic and complex biological systems such as seeds.

### 1.2.1 General concept of seed harvesting and sample preparation

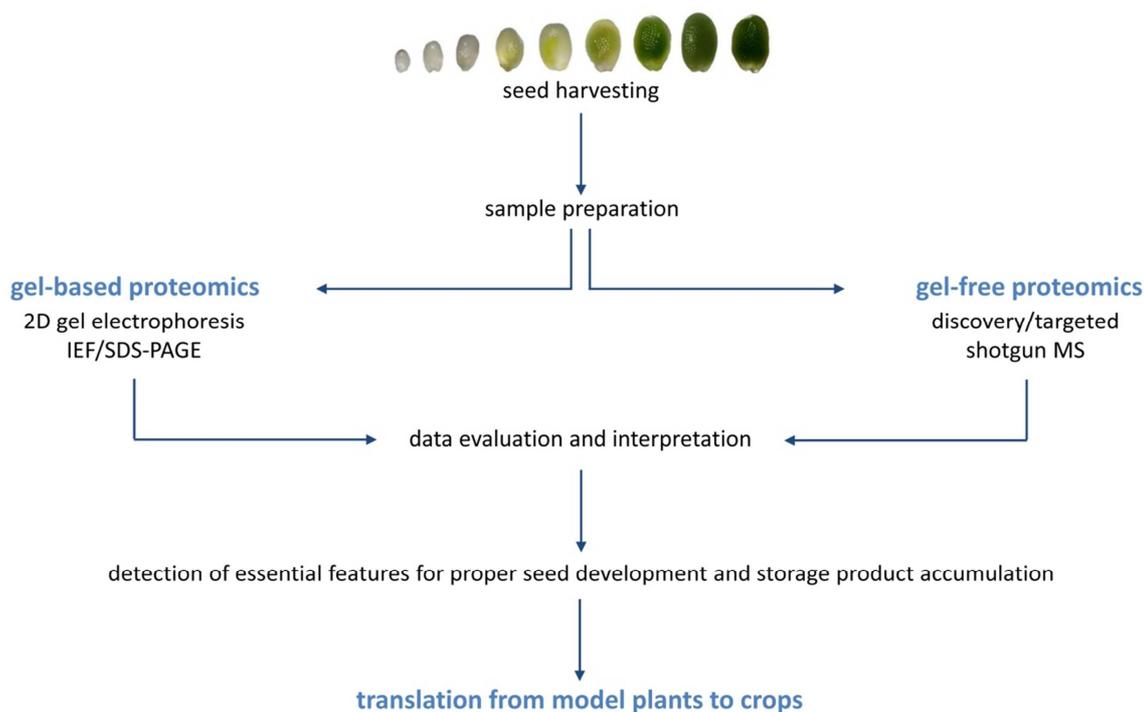

Harvest and analysis of developing seeds is not trivial. For comparative analysis it is necessary to ensure developmental and physiological uniformity of the seed samples. To investigate seeds of a specific developmental stage, flowers are labeled on the day of pollination and are harvested at time points specific for the developmental stages in question. In addition to flower tagging and time-dependent harvesting, developmental stages of seeds can be checked by light microscopy of the growing embryo ([Goldberg et al. 1994](#)). In most seed proteomic studies whole seeds have been used since seeds of model plants such as *Arabidopsis* are comparatively small and separation of the seed in its different tissues (for example endosperm and embryo) is difficult. [Schiebold et al.](#) (2011) were able to show that laser micro dissection is a powerful method to collect different tissues from a seed for comparative analysis. However, to study the biological function of different seed compartments species producing large seeds are favorable. The endosperm of *B. napus* seeds can be easily isolated during its development using a micro syringe and provides an excellent source for proteomic approaches aimed at investigating the impact of a transient tissue on development and storage product accumulation ([Lorenz et al. 2014](#), [chapter 2.1](#)). Sample preparation and protein extraction are critical steps to guarantee consistent and high quality proteomic data. Protein extraction from seed cells is a challenging task since the cells contain

compounds such as polyphenols, polysaccharides, starch, lipids and several secondary metabolites interfering protein separation methods such as gel electrophoresis and mass spectrometry (MS). In addition, storage proteins are present at high amounts while other proteins are comparatively low abundant in seeds. For total soluble proteins of seed samples an extraction method established by [Colditz et al. \(2004\)](#) has proven suitable and results in high-quality protein extracts. This method is based on protein solubilization in the phenol phase and several rounds of centrifugation followed by ammonium acetate precipitation to reduce interfering molecules in the sample. The major challenge is to analyse as many proteins as possible in a given sample. Proteins have diverse molecular characteristics such as molecular weight, isoelectric point, post translational modifications and hydrophobicity. The complexity of proteins and their dynamic range of concentration within seed samples can for example be reduced by sub-fractionation of different organs and tissues, e.g. endosperm and embryo ([Lorenz et al. 2014](#)). In order to analyse low abundant proteins during seed filling it is advantageous to deplete high abundant storage proteins from the sample ([Krishnan et al. 2009](#)). Many protocols have been established to analyse plant organellar proteomes such as chloroplasts ([Kubis et al. 2008](#)), mitochondria ([Keech et al. 2005](#)) and peroxisomes ([Eubel et al. 2008](#)). Nevertheless, to apply those protocols to seed samples they need to be adjusted for low amounts of seed material.

### 1.2.2 Gel-based versus gel-free proteomics

Gel-based proteomics represents the most popular approach of global separation and quantification of proteins and became a standard tool in many biological studies. Two dimensional gel electrophoresis (2D-GE) resolves approximately 1000 proteins per gel and enables simultaneous characterization of different biochemical properties such as isoforms and molecular mass. The analysis of quantitative changes of proteins is based on spot volumes followed by protein identification via mass spectrometry. However, gel based methods also have limits in terms of analysing high molecular weight proteins, alkaline proteins, hydrophobic proteins and low abundant proteins. In the recent years gel-free approaches such as shotgun mass spectrometry were established. Prior to analysis proteins are digested and the resulting complex peptide mixtures are separated by liquid chromatography and subsequently analysed by tandem MS (LC-MS/MS), which offers high throughput analysis of proteomes and provides information on protein quantities. Hence, considering gel-based and/or gel-free methods mainly relies on the biological question addressed. The continuous improvement of

proteomic methods largely contributed to the characterization of seed proteomes and elucidation of complex interaction networks (reviewed in Wang et al. 2014 and Hajduch et al. 2011). In this thesis gel-based as well as shotgun (gel-free) proteomics were implemented to unravel physiological transitions and regulatory mechanisms required for proper seed development and reserve deposition (Figure 2). In the future, this information could be translated from model plants to crops to increase seed quality and yield.

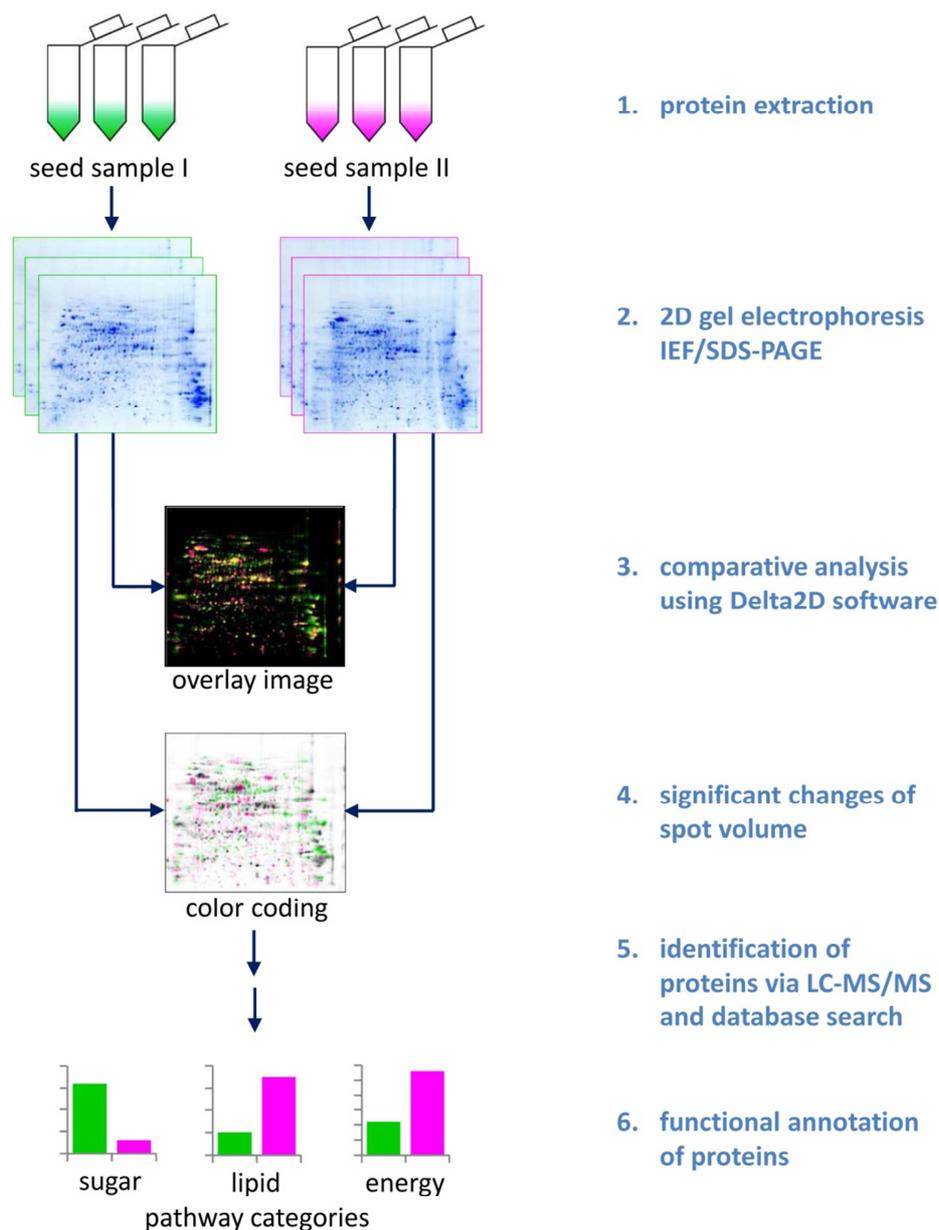

**Figure 2: Proteomics workflow towards understanding of developmental processes and storage product accumulation in seeds.** After isolation, seed proteins can be either analysed by gel-based or gel-free proteomics. The combination of both techniques delivers comprehensive information on essential features of seed formation and is able to identify the key proteins involved in this process, thereby revealing the biological mechanisms controlling tissue transition to seed filling. This information can be translated from model plants to crops to increase seed quality and yield. **2D**, two dimensional; **IEF/SDS-PAGE**, isoelectric focussing/sodium dodecylsulfate polyacrylamide gel electrophoresis; **MS**, mass spectrometry.

### *Comparative proteomic analysis using two dimensional gel electrophoresis*

A proteomic workflow including two dimensional gel electrophoresis with isoelectric focussing (IEF) in immobilized pH gradients (IPG) followed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), comparative analysis using gel analysis software and subsequent protein identification via LC-MS/MS has been established to analyse seed samples (Figure 3). Two dimensional gel electrophoresis delivers high resolution separation of different proteins including information on molecular masses, isoforms and post

translational modifications. The large number of simultaneously separated proteins characterizes the current biological state of different seed tissues or developmental stages. A known disadvantage of 2D gel electrophoresis is the low level of reproducibility due to differences in the gel runs that impede direct comparison of spot pattern of different 2D gels. Such gel to gel variations can be reduced by using differential gel electrophoresis (DIGE) that involves fluorescent labeling before protein separation, thereby allowing multiplexing of different seed samples (Hajdich et al. 2007). A positive side effect of this approach is an increased sensitivity (when compared to classical, non-fluorescent protein dyes such as coomassie). However, the multiplexing capacity is limited to the number of available fluorescent dyes. Several commercial and freely available software solutions can be used to analyse multiplexing and non-multiplexing IEF/SDS gels (e.g. Delta2D, Decyder, PD-Quest, Image Master 2D, Melanie, Same Spots). In the course of this thesis, the Delta2D software for gel image analysis and comparative proteomic approaches as described in Berth et al. (2007) was used. This software is able to match and relatively quantify protein spot volume from a large set of different samples. It has been shown that the advanced statistics and visualization methods included in Delta2D allow profiling of spot volumes and relative quantification of individual spots to predict metabolic pathways and functional dynamics in seed proteomes of different species. Physiological clustering of regulated proteins revealed new insights into endosperm function of *Brassica napus* (Lorenz et al. 2014, chapter 2.1) and *Cyclamen persicum* (Mwangi et al. 2013, chapter 2.3). The proteomic analysis of zygotic and somatic embryos of *Theobroma cacao* has been shown that carbohydrate metabolism especially glycolysis is of special importance for embryogenesis (Noah et al. 2013, chapter 2.4). These gel based proteomic studies therefore contributed in identifying quantitative changes of proteins that are particular important for developmental and metabolic processes in seeds.

**Figure 3: Workflow for gel based comparative proteomics.** The total soluble proteins are extracted from each seed sample (1) and separated by two dimensional (2D) IEF/SDS-PAGE (2). For statistical analyses at least three replicates per sample are required. The Delta2D software (Decodon) was used for the comparative quantitative analysis (3). First a digital overlay image of the samples is produced. Spots shown in green are of higher volume in seed sample 1 compared to seed sample 2, magenta spots are of reduced volume and yellow spots are of equal volumes. Statistically significant changes across all samples are marked in a color coding image (4). The proteins within the differentially abundant spots can be analysed via liquid chromatography (LC) followed by tandem mass spectrometry (MS/MS) and database search (5). Finally, functions of identified proteins are assigned to metabolic pathways (6). **IEF**, isoelectric focussing; **SDS**, sodium dodecylsulfate; **PAGE**, polyacrylamide gel electrophoresis.

### ***Shotgun mass spectrometry based proteomics***

Supported by the ongoing development of mass spectrometers with respect to mass accuracy and sensitivity the characterization of whole proteomes in a high throughput manner became feasible without the need for prior separation of proteins (Nilsson et al. 2010). A shotgun MS based proteomic workflow includes protein extraction and digestion with a protease e.g. trypsin. The resulting complex peptide mixture is separated by liquid chromatography and spectra of the mass-to-charge ratio of precursor peptide ions and fragment peptide ions are acquired by MS scans. The huge sample throughput and high sensitivity are major advantages of LC-MS/MS methods. In addition to the pure identification of proteins (discovery MS), quantitative shotgun MS methods were successfully established in the last years. It has been shown that label free shot gun proteomics can be applied to detect and relatively quantify peptides and therefore proteins in seed samples using high resolution instruments. Applying this method revealed new insights into the role of seed photosynthesis and amino acid metabolism during development (Lorenz et al. 2015, chapter 2.6). Label-free quantification methods include either peak integration of precursor ions or spectral counting of fragment ions (Cox et al. 2014, Zhu et al. 2010). Peak integration seems to produce more accurate results, whereas spectral counting is more sensitive (Old et al. 2005). Both methods are promising to give broad insights into differentially abundant proteins within two or more proteomes. However, bioinformatics and statistics are crucial steps also in quantitative shotgun MS proteomic approaches and specialized software tools have been developed such as MaxQuant (MQ), which integrates peptide peaks and matches them from multiple samples (Cox et al. 2008) and Proteome Discoverer (PD, Thermo Fisher Scientific) for spectral counting. More recently targeted proteomic approaches such as selective reaction monitoring (SRM) and targeted-selected ion monitoring (t-SIM) were developed to identify and quantify specific proteins of interest. Picotti et al. (2013) have shown that SRM mass spectrometry is a powerful tool and represents an alternative application to immune detection by the use of antibodies. This technique also termed 'mass-western' allows quantification of low abundant proteins in complex samples.

### 1.3 Insights into central metabolic pathways essential for proper seed development

During seed formation, changes in cellular structure coincide with distinct switches in metabolic activities. At early stages a metabolic cross-talk between the endosperm and embryo ensures cell differentiation and proper embryo growth. Later, the embryo massively accumulates storage compounds within the cotyledons which become a highly specialized storage tissue (Figure 4). Nutrients such as sugars and amino acids delivered from the mother plant are precursors for storage product biosynthesis in seeds (Melkus et al. 2009). In oilseeds like *A. thaliana* and *B. napus* mainly lipids and proteins are deposited during the seed filling phase. Only limited information on carbon storage in the cotyledons of oilseeds is available. At early stages, starch and hexoses (glucose and fructose) accumulate transiently, but their amount gradually decreases accompanied with a rapid increase of oil and lipid storage (Borisjuk et al. 2005, Baud et al. 2002). During germination, storage compounds are subsequently degraded and provided to the growing seedling. The efficiency of the storage compound mobilization depends on their amount accumulated during maturation and the action of distinct metabolic switches towards germination (Gallardo et al. 2008, Fait et al. 2006). The results obtained in the course of this thesis indicate that the activity of central metabolic pathways such as photosynthesis, mitochondrial metabolism and carbohydrate metabolism are essential for proper tissue formation and storage product synthesis during seed filling.

#### 1.3.1 Seed photosynthesis

Seeds of many different species are green during development, e.g. *B. napus* and *A. thaliana* contain photoheterotrophic plastids. The permeability of gases into seeds is rather low and plastidial activity during maturation phase contributes to oxygen allocation and re-assimilation of CO<sub>2</sub> (Borisjuk and Rolletschek 2009, Rolletschek et al. 2005, Borisjuk et al. 2005, Ruuska et al. 2004). Seed plastids hold special structures and have adapted their metabolism to cope with reduced light levels available for photosynthetic reactions (Borisjuk et al. 2013, Borisjuk et al. 2004). They have an elongated shape and contain high amounts of grana stacks and large starch grains (Asokanathan et al. 1997). The electron transport activity in seed plastids is different as shown by an enhanced chlorophyll a (Chla) to chlorophyll b (Chlb) ratio and high abundance of photosystem II (PSII) proteins, indicative of a cyclic electron transport via PSII. Highest photosynthetic activity is observed during storage product synthesis, suggesting a

correlation of metabolic processes and photosynthesis (Fait et al. 2006, Ruuska et al. 2002). In contrast to chloroplasts of leaves, seed plastids import carbon, mainly glucose-6-phosphate, phosphoenolpyruvate and pyruvate via specific transporters (Eastmond and Rawsthorne 1998). The enhanced activity of PSII in seeds contributes to O<sub>2</sub> supply needed for energy provision by redox equivalents and ATP (Borisjuk et al. 2005). At the same time, seed capacity of CO<sub>2</sub> fixation is rather low (Asokanthan et al. 1997). Hence, the metabolism of photoheterotrophic plastids in seeds is changed into the direction of fatty acid biosynthesis (Andriotis et al. 2010, Goffman et al. 2005). Therefore it is proposed that seed photosynthesis effects embryogenesis (Hsu et al. 2010) and consequently germination (Allorent et al. 2015).

### 1.3.2 Mitochondrial metabolism in seeds

Mitochondria are essential organelles with pivotal roles in many cellular processes such as tricarboxylic acid (TCA) cycle activity, oxidative phosphorylation and energy production (Millar et al. 2011). In addition to the previously described functions, seed mitochondria have special roles in stress response and desiccation tolerance during germination (Macherel et al. 2007). As seeds have very compact tissues, the capacity of gas exchange is rather low, requiring an adjustment of mitochondrial metabolism (Borisjuk et al. 2005). Mitochondrial activities in seeds are well adapted to promote storage product accumulation (Vigeolas et al. 2003). It is assumed that embryos of *B. napus* seeds hold an unconventional mitochondrial metabolism since the cyclic flux around the TCA cycle is absent and substrate oxidation is reduced and hardly contributes to ATP production. Furthermore, isocitrate dehydrogenase activity is reversible and malic enzyme activity is enhanced (Schwender et al. 2006). Recently it was postulated that amino acids are not only building blocks for storage proteins within seeds, but also serve as alternative substrates for mitochondrial metabolism during stress situations (Galili et al. 2014, Fait et al. 2006). In vegetative tissues, amino acid catabolism is induced by carbon starvation situations e.g. periods of extended darkness (Hildebrandt et al. 2015, Araujo et al. 2011 and 2010). First studies denote a potential role of amino acid catabolism to the energy status in seeds (Krübel et al. 2014, Credali et al. 2013, Angelovici et al. 2011, Gu et al. 2010, Angelovici et al. 2009, Weigelt et al. 2008, Zhu and Galili 2003). It is likely that also in seeds together with photosynthesis amino acid degradation presumably contributes to energy provision. It has been shown that in *Arabidopsis* leaves a mitochondrial sulfur dioxygenase, is part of a sulfur catabolic pathway that catalyses the oxidation of sulfide or persulfides derived from amino acids to thiosulfate and sulfate and has key functions in

amino acid catabolism (Höfler et al. 2015, chapter 2.5, Krübel et al. 2014). In seeds, ETHYLMALONIC ENCEPHALOPATHY PROTEIN1 (ETHE1) knock out leads to alterations in endosperm formation and finally causes seed abortion (Holdorf et al. 2012). It has been shown that a sulfur dioxygenase activity of 1 % present in an ETHE1 knock down mutant (*ethe1-1*) is sufficient for embryo survival, but development is severely delayed (Krübel et al. 2014), which underlines the importance of this enzyme for seed development. A first detailed investigation on the function of the mitochondrial sulfur dioxygenase ETHE1 in seeds supports the hypothesis that amino acid metabolism is pronounced and has a potential role in nitrogen and energy provision during seed development (Lorenz et al. 2015, chapter 2.6).

### 1.3.3 Carbohydrate metabolism of developing seeds

Proteomic investigations of seed metabolism in different species have shown that carbohydrate metabolism is of central importance and has pivotal roles in development including seed filling, stress response and signal transduction (Lorenz et al. 2014, chapter 2.1; Mwangi et al. 2013, chapter 2.3; Noah et al. 2013, chapter 2.4). Sugars are degraded within a seed which is initially realized by invertases and sucrose synthases (Hill et al. 2003). Invertases also have a regulatory role in tissue formation by enhancing cell division whereas sucrose synthase activity affects biosynthesis of cellulose, proteins, lipids and starch in seeds (Wang and Ruan 2013, Xu et al. 2012, Pugh et al. 2010, Fallahi et al. 2008, Ruan et al. 2008, Chourey et al. 1998). At very early stages of seed development, vacuolar invertases are able to convert imported sucrose into hexoses in the endosperm and provide them to the growing embryo. The accumulation of hexoses subsequently drives water and nutrient uptake of the seed. Afterwards the cellularization of the endosperm causes shrinkage of the central vacuole and the ratio of hexoses and sucrose is switched (Hehenberger et al. 2012, Moreley-Smith et al. 2008). During later stages of development sucrose accumulates in the seeds. The switch from high hexose to high sucrose level is related to differentiation, cell expansion and storage activity in the embryo (Rolland et al. 2006, Weber et al. 2005). Thus, the embryo is able to develop into a self-competent sink tissue within the seed. Hexoses can be metabolized in the cytosol and in plastids either by glycolysis or oxidative pentose phosphate pathway (OPPP) to provide precursors for fatty acid biosynthesis (Schwender et al. 2003). Beyond these two pathways, Schwender et al. (2004) discovered that green seeds are able to contribute to fatty acid (FA) precursor formation by the activity of a ribulose-1,5-bisphosphate

carboxylase/oxygenase (RuBisCO) -bypass. In this unique pathway, RuBisCO is able to act without the Calvin cycle in a so far unknown reaction to improve carbon efficiency in seeds. Acetyl-CoA, a metabolite taking part in various metabolic reactions, is needed for proper seed development and storage product deposition (Ke et al. 2000). It is proposed that several enzymes like NADP-dependent malic enzyme (ME) (Shearer et al. 2004), plastidial acetyl-CoA synthase (Lin and Oliver 2008), cytosolic phosphoenolpyruvate carboxylase (PEPC) (Sebei et al. 2006), NAD-dependent malic enzyme (MDH) (Junker et al. 2007) and ATP citrate lyase (Rawsthorne 2002) contribute to fatty acid biosynthesis in seeds. However, the regulation of carbon flux into fatty acid production by the proposed pathways is complex and their specific activity *in vivo* needs to be further investigated. In addition to providing carbohydrates for metabolism and storage product accumulation, sugars hold special functions in signal transduction (Hanson and Smeekens 2009). Sugar signal molecules like glucose, fructose, and trehalose-6-phosphate may modulate development. Defective sucrose metabolism and signaling trigger stress responses and reproductive failure (O'Hara et al. 2013, Ruan et al. 2008). It is proposed that low glucose levels inhibit cell division (Wang and Ruan 2013, Weber et al. 2005) and induce over-production of reactive oxygen species due to reduced hexokinase activity (Kim et al. 2006). Investigations on mutants indicate a considerable role of glycolytic enzymes on plant development, growth and storage product biosynthesis (Dorion et al. 2012, Chen and Thelen 2010, Muñoz-Bertomeu et al. 2010 and 2009, Andre and Benning 2007, Lee et al. 2002, Plaxton 1996). It is postulated that the occurrence of a nucleotide sugar recycling pathway is essential for vegetative and reproductive growth in *A. thaliana*. Due to cellularization of the endosperm, nucleotide sugars are important cell wall monomers that represent substrates for the turnover of cell wall polymers at later stages of seed development (Geserick and Tenhaken 2013).

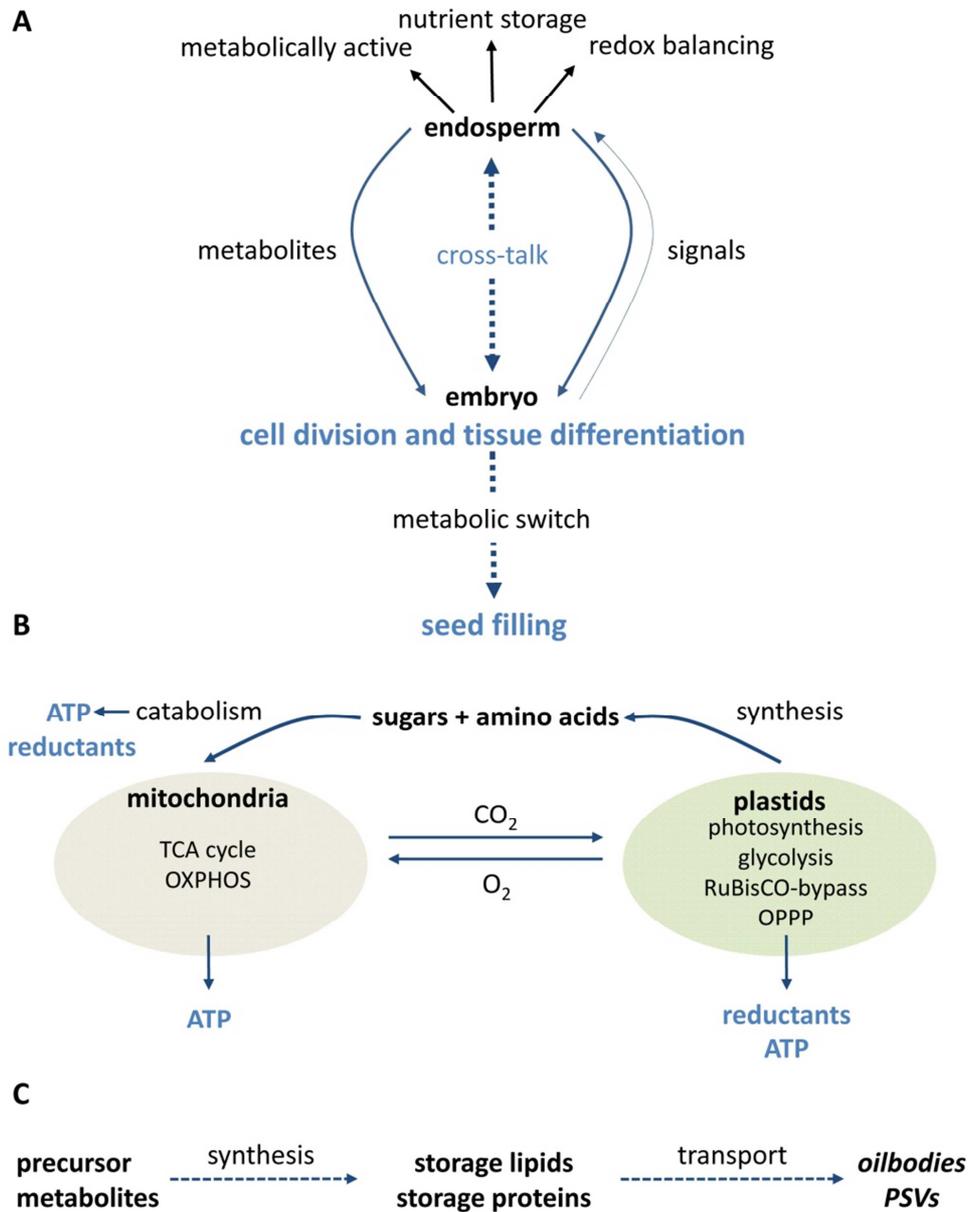

#### 1.3.4 Storage lipid biosynthesis

In seeds storage lipids are accumulated in form of triacylglycerols (TAGs) and fatty acids (FAs) (Gallardo et al. 2008, Murphy and Cummins 1989). Predominant FAs in seeds are palmitate, stearate, oleate, linoleate and alpha-linoleate (Voelker and Kinney 2001). Oilseeds like *B. napus* are enriched with very long chain FAs (VLCFA) (Sharafia et al. 2015). FA biosynthetic pathways in plants are well characterized (Baud and Lepiniec 2009, Rawsthorne 2002) and strongly dependent on the supply of energy, reductants and carbon sources (see chapter 1.3.3). Sucrose delivered from the mother plant is sequentially metabolized by

pathways in the cytosol and the plastids to produce fatty acids (Hills 2004). The first committed step is catalyzed by an acetyl-CoA carboxylase (ACCase) which carboxylates acetyl-CoA to form malonyl-CoA. The assembly of FAs occurs at the acyl carrier protein (ACP). The resulting acyl-ACP can either be hydrolyzed by acyl-ACP thioesterases or further elongated by specific condensing enzymes, the 3-ketoacyl-ACP synthases (KAS). The biosynthesis of FAs is mainly regulated by interactions of transcriptional regulation and optimization of enzyme activity (Baud and Lepiniec 2009, Ohlrogge and Jaworski 1997). FAs are transported into the ER where they may subsequently be desaturated (Baud and Lepiniec 2009), prior to their esterification to a glycerol backbone and being transferred to dedicated storage organelles so called 'oil bodies' (Huang 1992). The biosynthesis of seed storage lipids is a potential target for metabolic engineering in an attempt increasing their content of healthy FAs, improve oil stability and generally increase oil content (Thelen and Ohlrogge 2002).

### 1.3.5 Seed storage protein accumulation

Seed storage proteins (SSPs) accumulate during the seed filling phase and are a major source of nitrogen and amino acids. The composition of storage proteins varies between different species. In the dicotyledons *Arabidopsis* and *B. napus* the mature seeds contain globulins (cruciferin), albumins (napin) and oleosins (oil body protein) (Höglund et al. 1992, Huang 1992) with cruciferins accounting for the bulk (approximately 60 %) of the total seed protein content (Crouch and Sussex 1981). Globulins are co-translationally synthesized into the rough endoplasmic reticulum (rER). The mature protein consists of an  $\alpha$ - and a  $\beta$ -polypeptide chain linked by a disulfide bond. Both chains are derived from the same precursor molecule and the proglobulin is newly assembled into trimers by cleavage of the ER signal peptide followed by formation a disulfide bond between the N- and C- terminus of the polypeptide (Ereken-Tumer et al. 1982, Chrispeels et al. 1982, Sengupta et al. 1981). The formation of trimers is essential for a directed transport from the ER into protein storage vacuoles (PSVs) (Chrispeels et al. 1982). After import the trimers are disassembled, which is realized by a vacuolar processing enzyme, and organized into hexamers to form the mature protein (Dickinson et al. 1989, Jung et al. 1998, Shimada et al. 2003). In contrast to previous reports on globulin complexes, the native *B. napus* cruciferin complex exhibits a unique octameric barrel-like structure. This structure represents a very compact building block optimized for maximal storage of amino acids (Nietzel et al. 2013, chapter 2.2).

**Figure 4: Essential features of developing seeds needed for proper tissue differentiation and storage product synthesis.** At early stages a metabolic cross-talk between the endosperm and embryo ensures cell differentiation and proper embryo growth (A). Later the metabolism of the seed is switched to storage product accumulation. This process is marked by an increase of central metabolic pathways in cytosol, mitochondria and plastids (B). The provision of sufficient amounts of precursor molecules, reductants and energy highly influence the composition of stored lipids (*oilbodies*) and proteins (*PSVs*) (C). **ATP**, adenosine triphosphate; **CO<sub>2</sub>**, carbon dioxide; **O<sub>2</sub>**, oxygen; **OPPP**, oxidative pentose phosphate pathway; **OXPHOS**, oxidative phosphorylation; **PSV**, protein storage vacuole; **RuBisCO**, ribulose-1,5-bisphosphate carboxylase/oxygenase; **TCA**, tricarboxylic acid.

## 1.4 Objectives of the thesis

The overall aim of this thesis was to increase our understanding of seed biology and create a deeper knowledge of the physiological role of differentially regulated proteins during tissue differentiation and storage product accumulation. A detailed characterization of regulated metabolic pathways and the identification of developmental and tissue specific proteins using proteome analyses allowed identifying molecular events of key importance for seed biology. The new insights will be of relevance for improving seed quality and yield in the future.

This thesis was focused on the following objectives:

- (i) Establishment of a comparative proteomic workflow for investigating seed development and storage product accumulation in different species
- (ii) Detailed analysis of endosperm function and metabolism to characterize its contribution to seed development
- (iii) Characterization of the native cruciferin complex, a highly abundant storage protein complex in *Brassica napus*
- (iv) Investigation of photosynthesis and amino acid metabolism in developing seeds

### ABSTRACT

Oilseeds are an important element of human nutrition and of increasing significance for the production of industrial materials. The development of the seeds is based on a coordinated interplay of the embryo and its surrounding tissue, the endosperm. This study aims to give insights into the physiological role of endosperm for seed development in the oilseed crop *Brassica napus*. Using protein separation by two-dimensional (2D) isoelectric focusing (IEF)/SDS polyacrylamide gel electrophoresis (PAGE) and protein identification by mass spectrometry three proteome projects were carried out: (i) establishment of an endosperm proteome reference map, (ii) proteomic characterization of endosperm development and (iii) comparison of endosperm and embryo proteomes. The endosperm proteome reference map comprises 930 distinct proteins, including enzymes involved in genetic information processing, carbohydrate metabolism, environmental information processing, energy metabolism, cellular processes and amino acid metabolism. To investigate dynamic changes in protein abundance during seed development, total soluble proteins were extracted from embryo and endosperm fractions at defined time points. Proteins involved in sugar converting and recycling processes, ascorbate metabolism, amino acid biosynthesis and redox balancing were found to be of special importance for seed development in *B. napus*. Implications for the *seed filling* process and the function of the endosperm for seed development are discussed.

#### Biological significance

The endosperm is of key importance for embryo development during seed formation in plants. We present a broad study for characterizing endosperm proteins in the oilseed plant *B. napus*. Furthermore, a project on the biochemical interplay between the embryo and the endosperm during seed development is presented. We provide evidence that the endosperm includes a complete set of enzymes necessary for plant primary metabolism. Combination of our results with metabolome data will further improve systems-level understanding of the *seed filling* process and provide rational strategies for plant bioengineering.

## 1. Introduction

The endosperm is a central compartment of the developing plant seed. It embeds the embryo and is surrounded by the seed coat. Seed development is initiated by a double fertilization: (i) fertilization of an egg cell by a sperm cell, which leads to the embryo and (ii) fertilization of a diploid central cell by another sperm cell, which gives rise to the triploid endosperm.

Seed formation of dicotyledonous species such as *Arabidopsis thaliana* and *Brassica napus* is characterized first by a stepwise differentiation of the endosperm including transition from a syncytial to a cellular phase [1–4] followed by embryo development. The formation of a syncytium is initiated by several rounds of mitosis of the fertilized central cell without cytokinesis leading to a multinuclear cell [1]. In the course of seed development the endosperm is divided into three mitotic domains: (1) the micropylar, (2) the peripheral and (3) the chalazal region in which nuclei divide simultaneously [5]. The syncytium becomes cellularized by the formation of radial microtubule systems starting from the micropylar region [1,4,6]. The process of cellularization has a great impact on the accurate embryo development [7] and leads to the initiation of cotyledon growth [4]. After cellularization the outermost cells of the endosperm differentiate into the aleurone layer. The characteristics of this cell type are thick cell walls and the deposition of storage compounds and enzymes [8]. In dicotyledons the endosperm is of transient nature and only the aleurone layer remains until seed maturity whereas the bulk of the endosperm is replaced by the growing embryo. Programmed cell death leads to the degradation of endosperm cells and is probably controlled by ethylene and interactions between embryo and endosperm [9–11]. The interplay of different seed compartments on various molecular and genetic levels is crucial for coordinated seed development [12–16].

Investigations of mutants carrying endosperm specific defects have given insights into development and function of this compartment [7,17–21]. Most of these studies were focused on plant species exhibiting a constitutive endosperm like cereals. In these monocotyledonous plants, the endosperm has a prime role in storage compound accumulation [22–28], while in dicotyledonous species the endosperm rather seems to play a transient role. It nourishes the embryo and supports development and growth at early seed developmental stages [4,9,29,30]. Here, storage compounds are rather accumulated in the cotyledons [31]. The endosperm is the main source of carbohydrates and amino acids for the growing embryo [32]. At very early stages of seed development sucrose imported from the mother plant is cleaved into hexoses in the endosperm and provided to the embryo. Accumulation of hexoses subsequently drives water and nutrient uptake of the seed [33]. During later stages of development sucrose accumulates in the seeds. The switch from high hexose to high sucrose level is related to differentiation, cell expansion and storage activity in embryo [34,35]. The endosperm represents the direct environment of the dicot embryo and ensures constant and optimal conditions for its differentiation and growth [32]. However, the metabolic

functions ensuring its evolutionary mission are just beginning to emerge [36–38]. It is particularly unknown to which extend endosperm metabolism can modulate the incoming stream of assimilates, and thereby affect differentiation, growth and storage functions of the embryo.

In this study a comparative proteomic strategy was applied to developing seeds of *B. napus*. This plant represents one of the most important oilseed crops. Based on (i) the establishment of an endosperm proteome reference map, (ii) the proteomic characterization of endosperm development, and (iii) the comparison of endosperm and embryo proteomes, we aimed to get insights into both physiology and metabolic functions of endosperm in dicot seeds.

## 2. Material and methods

### 2.1. Cultivation of *B. napus* seedlings and seed tissue preparation

*B. napus* plants were grown under the following conditions: 16-h light (16 klx) at 22 °C, 8-h dark at 18 °C with a relative humidity of 55%. Our experimental set up was the following: For each experiment, 10 rapeseed plants were used. Approximately 25 siliques were harvested per plant and approximately 30 seeds per silique (overall approximately 7500 seeds per experiment). Embryo and endosperm fractions were prepared manually. The procedure was repeated at three times points per fraction (endosperm: 10, 15 and 20 days after pollination [DAP], embryos 15, 20 and 25 DAP). All 10-plant experiments for all time points were carried out twice. The endosperm fractions were isolated with a microsyringe from the seeds. Embryos were isolated by removing the seed coat and subsequent washing to remove the potentially remaining endosperm. The endosperm was directly used for phenolic extraction of proteins. In contrast, the embryos were first pulverized using a bead mill.

### 2.2. Phenolic extraction of proteins and two dimensional (2D) IEF/SDS PAGE

Total soluble proteins were extracted from the endosperm and embryo fraction according to Colditz et al. [39]. Briefly, endosperm and pulverized embryo fractions were homogenized in extraction buffer (700 mM sucrose, 500 mM Tris, 50 mM EDTA, 100 mM KCl, 2% (v/v)  $\beta$ -mercaptoethanol and 2 mM PMSF, pH adjusted to 8.0). Then, saturated phenol (pH 6.6/7.9; Amresco, Solon, USA) was added. After several rounds of centrifugation proteins were precipitated with 100 mM ammonium acetate in methanol at –20 °C overnight. The resulting protein pellets were resuspended in resuspension buffer (8 M urea, 2 M thiourea, 2% (w/v) CHAPS, 100 mM DTT, 12  $\mu$ l/ml DeStreak-reagent, 0.5% (v/v) IPG-buffer pH 3–11 NL, GE Healthcare, Freiburg, Germany) and directly loaded onto an IPG strip (24 cm, pH 3–11 NL, GE Healthcare, Freiburg, Germany). Isoelectric focusing was performed as described in Mihr and Braun [40]. Second gel dimensions (precast 12.5% polyacrylamide gels, Serva Electrophoreses, Heidelberg, Germany) were performed using the HPE FlatTop Tower system (Serva Electrophoresis, Heidelberg, Germany) according to the manufacturer's guidelines. 2D analyses for endosperm

and embryo fractions (three time points each) were repeated at least three times.

### 2.3. Gel staining procedure

All 2D gels were fixed with 10% (v/v) acetate in 40% (v/v) methanol for 45 min and stained with Coomassie blue CBB G-250 (Merck, Darmstadt, Germany) as described by Neuhoff et al. [41,42].

### 2.4. Quantitative gel analyses of endosperm and embryo proteomes

Coomassie colloidal stained gels were first scanned and then analyzed by using the Delta2D software 4.3 (Decodon, Greifswald, Germany) with three replicates for each seed tissue (endosperm and embryo) and developmental stage (10, 15, 20 DAP for endosperm and 15, 20, 25 DAP for embryo fractions) according to Berth et al. [43]. Spots were detected automatically (minor corrections of obvious gel disturbances were performed manually). To determine significant alterations in spot abundance of endosperm and embryo fractions, a Student's t-test ( $p$ -value  $\leq 0.05$ ) was applied on the basis of normalized relative spot volume. Alterations in protein volumes between the compared fractions  $\geq$  factor 1.5 were considered to represent true differences on protein levels. Mean of normalized relative spot volume and coefficient of variation for each analyzed sample group are given in Supplementary Table 1. In order to analyze the similarity of the sample replicates a principal component analysis (PCA) was performed using Delta2D analysis following the manufacturer's instructions (for 3D plot of the samples see Supplementary Fig. 11). Additionally a heatmap using hierarchical cluster analysis (HCL) was generated using Delta2D software (Supplementary Fig. 12).

### 2.5. Mass spectrometry analysis of *B. napus* seed tissue proteins

The establishment of an endosperm proteome reference map and the analyses of changes in protein abundances during endosperm and embryo development were based on protein identifications by mass spectrometry (MS). Tryptic digestion and MS analysis was performed according to Klodmann et al. [44] using the EASY-nLC System (Proxeon) coupled to a MicroTOF-Q II mass spectrometer (Bruker Daltonics, Bremen, Germany). Identification of proteins was carried out using the MASCOT search algorithm ([www.matrixscience.com](http://www.matrixscience.com)) against the (i) SwissProt ([www.uniprot.org](http://www.uniprot.org)), (ii) NCBI nr ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)) and (iii) TAIR ([www.arabidopsis.org](http://www.arabidopsis.org), TAIR release 10) databases. In some cases, *B. napus* sequences are available. However, most proteins were identified via *A. thaliana*. *B. napus* and *A. thaliana* both belong to the Brassicaceae family and sequence identity within exons on average is above 90%. Therefore, the protein sequences of *Arabidopsis* are very useful for protein identifications in rapeseed. Identified proteins in *B. napus* are considered to represent homologs of the corresponding proteins in *Arabidopsis* (which does not exclude that they have differing functional roles). For details on peptides used for protein identification see Supplementary Table 2.

Identified proteins were functionally classified according to the KEGG PATHWAY Database (<http://www.genome.jp/kegg/pathway.html>). The pathway categories were adjusted for seed metabolism by adding four functional groups: (i) storage, (ii) defense, (iii) desiccation and (iv) detoxification.

## 3. Results and discussion

### 3.1. Characterization of the endosperm proteome

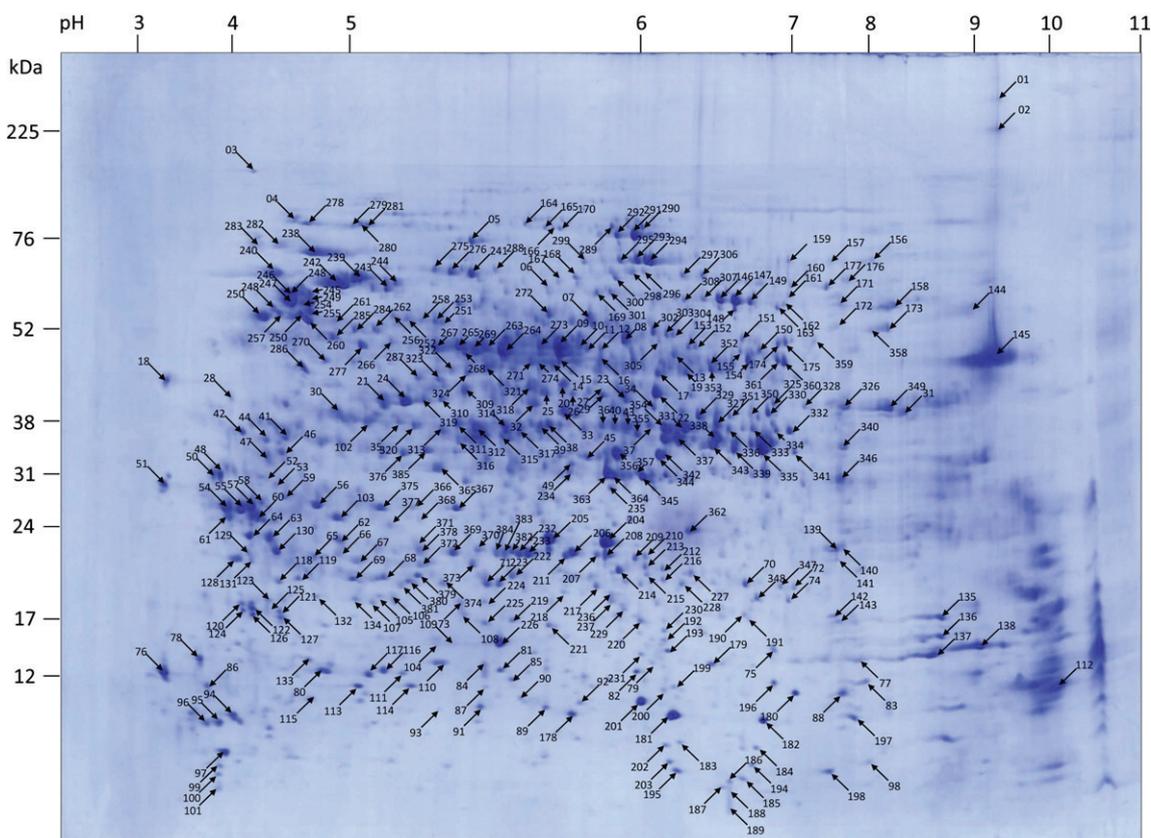

Soluble proteins were extracted from the endosperm harvested 20 days after pollination (DAP), separated by high resolution 2D IEF/SDS PAGE using the HPE FlatTop Tower gel electrophoresis system and resolved proteins were finally identified by mass spectrometry. Delta2D analysis revealed separation of 964 protein spots on our gels. 385 spots were selected on a random basis and represent the most abundant protein spots of all areas of the gel and resulting in the identification of 930 distinct endosperm proteins (Supplementary Table 1). It should be noted that, based on our experimental approach, the proteome of the endosperm is only partially covered. Results of our study were used to generate a 'reference map' of the *B. napus* endosperm proteome (Fig. 1). Identified proteins were systematically analyzed by usage of various database resources.

#### 3.1.1. Insights into overall proteome architecture

The *B. napus* endosperm proteome (Fig. 1) is composed of proteins covering a wide range of molecular masses (Fig. 2A) and pIs (Fig. 2B). Proteins within the 10 to 70 kDa range are predominant in the endosperm. Analysis of isoelectric points (pIs) of the identified proteins revealed two peaks, a major one at acidic to the neutral pH (pH 4.5 to 7.5) and a minor one at basic pH (pH 8.5–11). Apparent molecular masses of the 930 proteins very much correlate with calculated molecular masses (Fig. 2C). However, as expected, several proteins have a slightly reduced apparent molecular mass if compared to the calculated mass, which is due to the cleavage of targeting peptides of proteins transported to the endoplasmic reticulum (ER), chloroplasts or mitochondria. Only a few proteins on our 2D gels are significantly smaller than predicted, most likely reflecting proteolytic processing. A few proteins are larger than expected which could be the consequence of protein modification. Likewise, measured and calculated isoelectric points (pIs) of the 930 proteins correlate (Fig. 2D). However, several proteins clearly exhibit more acidic pIs than calculated, which most likely is due to protein modifications like phosphorylation.

#### 3.1.2. Functional classification of proteins abundant in the endosperm

The endosperm of *B. napus* includes a broad spectrum of proteins (Supplementary Table 1). To gain insights into endosperm metabolism, identified proteins were grouped into functional categories according to KEGG PATHWAY Database (Fig. 3). In the following sections, details on the predominant functional categories (i) genetic information processing (31% of the total set of identified proteins), (ii) carbohydrate metabolism (17%), (iii) environmental information processing

**Fig. 1 – Two-dimensional endosperm proteome reference map. Total soluble endosperm proteins were separated on a 3–11 NL pH gradient IPG strip and subsequently on a 12.5% SDS-PAGE. The gel was stained with colloidal Coomassie brilliant blue G250. The arrows indicate spots that were picked for MS analysis (for results see Supplementary Table 1). Molecular masses of standard proteins are given to the left and pIs above the gel.**

(12%), (iv) energy metabolism (9%), (v) cellular processes (7%) and (vi) amino acid metabolism (6%) are given:

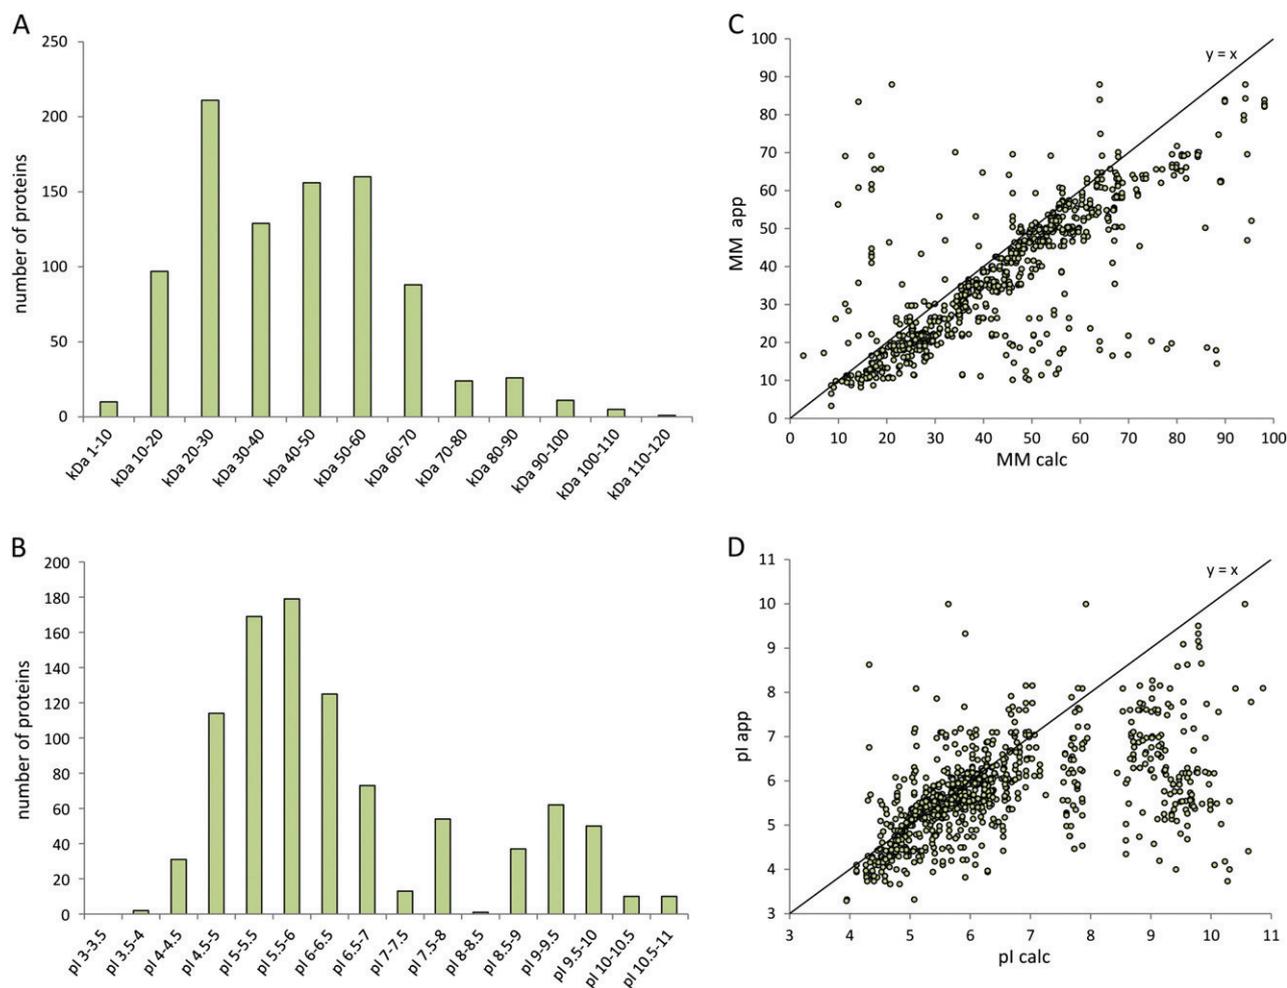

(i) *Genetic information processing*

The endosperm proteome includes a high number of proteins taking part in transcription and transcriptional regulation, like DEAD box RNA helicases, G-rich RNA-binding proteins, DNA-binding protein BIN4, regulator of ribonuclease-like protein 1, FACT complex subunit and rho termination factor. BIN4 is a component of the plant DNA topoisomerase. It has been discussed that expression of bin4 drives cell expansion [45]. Several transcription factors (AP2-like ethylene-responsive transcription factor BBM, basic transcription factor 3, GRAS transcription factor, WRKY transcription factor, squamosa promoter binding protein-like, SSXT family protein) were found in the endosperm. AP2-like ethylene-responsive transcription factor BBM promotes cell proliferation, differentiation and morphogenesis and leads to the induction of embryo development [46]. Also WRKY and GRAS transcription factors are proposed to control developmental processes [47,48]. Transcription factors expressed in the endosperm are known to control final seed size and to coordinate embryo development [49]. The factors identified here might be involved in this regulatory

cascade and/or related processes in *B. napus* seeds. Many proteins involved in translation, such as ribosomal proteins, initiation factors, elongation factors, and poly(A) binding protein, were identified in the course of our study. Proteins related to protein folding and sorting were found in several protein spots, for instance diverse chaperones, heat shock proteins and protein disulfide isomerases. The presence of numerous proteins involved in protein degradation, e.g. subunits of the proteasome and several monomeric proteases, indicates high protein turnover in the endosperm. The cell division control protein 48, an ATPase associated with versatile cellular functions [50], and the aspartic protease phytepsin are known to play important roles in targeted degradation of proteins.

(ii) *Carbohydrate metabolism*

Proteins involved in carbohydrate metabolism, which for instance play a role in glycolysis/gluconeogenesis, tricarboxylic acid (TCA) cycle and other sugar converting processes, are highly abundant in the endosperm. All glycolytic enzymes as well as the pyruvate dehydrogenase complex were identified. Glycolytic activity is one of the key features

**Fig. 2 – Proteome structure of *B. napus* endosperm. A: Distribution of calculated molecular masses of identified endosperm proteins. B: Distribution of calculated isoelectric points of identified endosperm proteins. C: Correlation of apparent and molecular masses. D: Correlation of apparent and calculated isoelectric points (pIs). Evaluations are based on a set of 930 identified proteins. Regression lines ( $y = x$ ) are given in C and D.**

of endosperm metabolism in *B. napus* seeds because it generates metabolic intermediates, reductants and energy [51]. *B. napus* embryos were reported to have a reduced cyclic flux around the TCA cycle [52]. In our study we only identified five out of the eight enzymes of the TCA cycle in the endosperm (aconitase, citrate synthase, isocitrate dehydrogenase, malate dehydrogenase and succinyl-CoA-ligase). Possibly the *B. napus* endosperm also has a reduced TCA cycle or the missing enzymes are beyond the detection limit of our study. Identification of enzymes contributing to the acetyl-CoA pool (2-oxoacid dehydrogenase acyltransferase, citrate lyase) might point to the high demand of acetyl-CoA for the synthesis of elongated fatty acids (and other compounds) which are highly abundant in rapeseed endosperm [53]. Furthermore the endosperm exhibits a high potential to produce reductant (NADH) via the pentose phosphate pathway as indicated by the detection of ribose-5-phosphate isomerase, phosphogluconate dehydrogenase, glucose-6-phosphate 1-dehydrogenase, 6-phosphogluconolactonase,

transaldolase and transketolase. Two enzymes related to ascorbate biosynthesis were identified (ascorbate peroxidase, dehydroascorbate reductase). The endosperm also exhibits an active starch metabolism as indicated by the presence of enzymes required for starch synthesis (AGPase) and starch degradation (beta amylase). These data altogether indicate an active biosynthetic machinery, and correspond to the histological detection of starch granules, storage protein vacuoles and oil bodies in rapeseed endosperm [53].

### (iii) Environmental information processing

The endosperm is the direct environment for the growing embryo and therefore is proposed to have a protective role. Accordingly, it includes a large number of proteins involved in signal transduction, plant hormone biosynthesis, stress response and defense related enzymes. The endosperm signaling pathways include annexin, calmodulin and 14-3-3

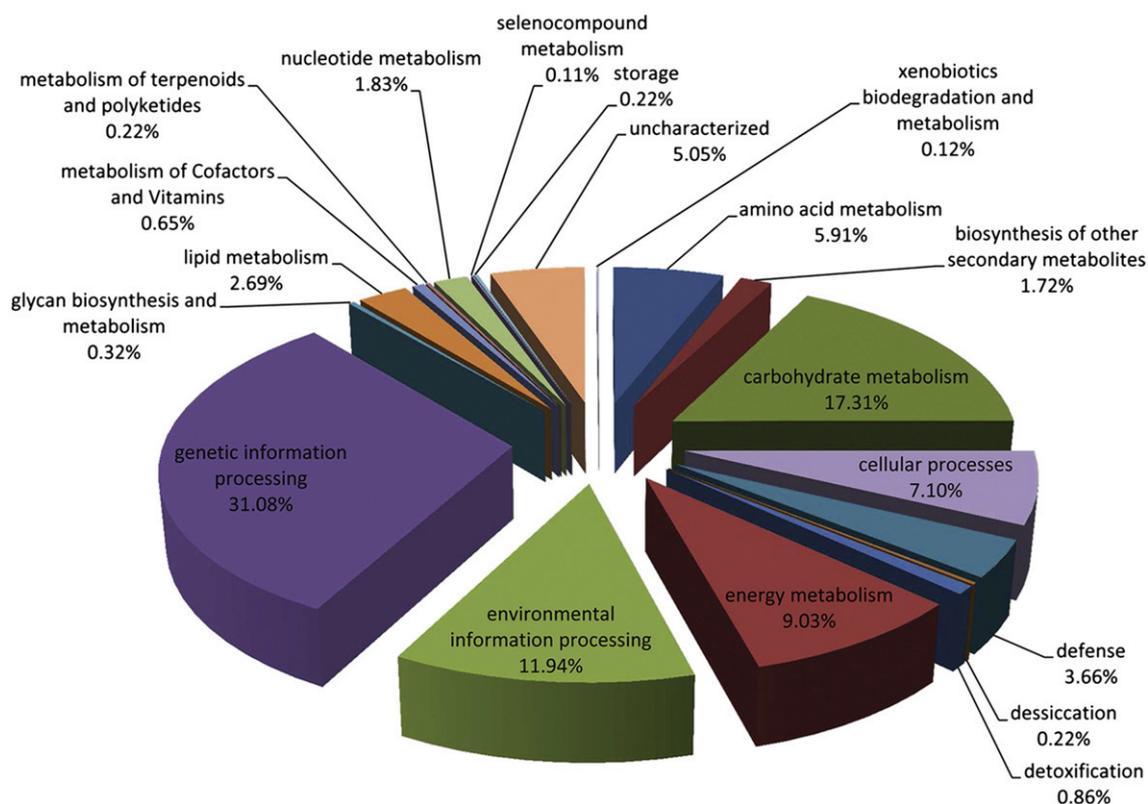

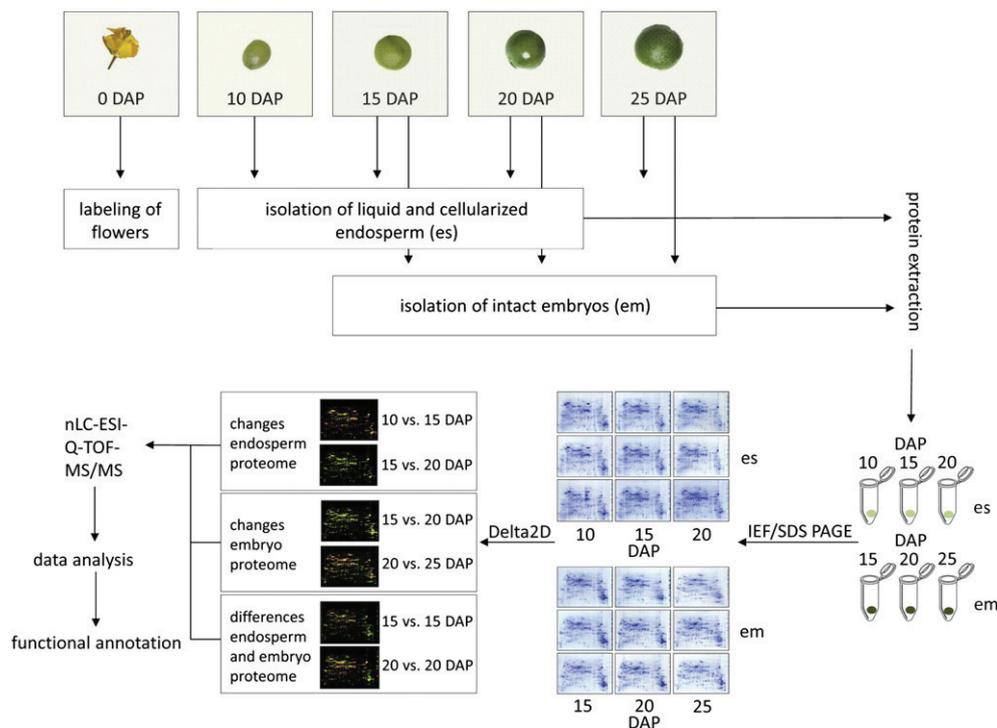

Fig. 3 – Functional classification of identified endosperm proteins of the proteome reference map. Proteins were assigned to the functional categories of the KEGG PATHWAY Database or one of the four following extra categories: (i) storage, (ii) defense, (iii) desiccation and (iv) detoxification.

Fig. 4 – *B. napus* seed development. Images of pods, whole seeds, seed cross-sections and embryos were taken from 7 to 56 DAP. Proteome analyses were carried out for 10 DAP (endosperm), 15 and 20 DAP (endosperm and embryo) and 25 DAP (embryo).

**Fig. 5 – Experimental strategy for proteomic characterization of early seed development. Flowers were tagged directly after pollination (0 DAP) to define developmental stages. Endosperm (es) and embryo (em) fractions obtained at 10–25 DAP were used for phenolic protein extractions followed by 2D IEF/SDS gel electrophoreses (three replicates for each fraction) Delta2D analysis was used for protein quantification. Proteins differing in abundance between the compared fractions were identified by MS analyses and assigned to functional categories.**

proteins. Calmodulin is a calcium binding protein and plays a role in varying signaling pathways [54]. Annexin, another calcium-binding protein, is able to build ion channels by forming a hexameric structure [55]. It possibly represents a regulator of ion exchange between subregions of the seed. Calcium-mediated signal transduction pathways might represent an important feature of the endosperm to coordinate developmental processes. Also, conserved regulatory 14-3-3 proteins were identified in this study which possibly are involved in seed development and germination [56]. The endosperm is also a source for plant hormones at maturation [57] but their role for endosperm development remained unknown so far. The following proteins involved in plant hormone biosynthesis were identified: auxin-responsive GH3 family protein, cytokinin riboside 5'-monophosphate phosphoribohydrolase LOG8, cytokinin-O-glucosyltransferase 1 and jasmonic acid-amido synthetase JAR1. Endosperm function in protecting the growing embryo might rely, besides other factors, on the occurrence of glutathione S-transferase, glutathione synthetase, glutaredoxin, catalase, peroxiredoxin, superoxide dismutase, translationally controlled tumor protein and adenine nucleotide alpha hydrolase, which all were identified in the course of our study. Also, plant defense related proteins, such as beta glucosidase, actin depolymerizing factors, protein LIR18A and thiocyanate methyltransferase were abundant in the endosperm. It is known that the termination of endosperm development is initiated by a gradual degradation of endosperm cells due to programmed

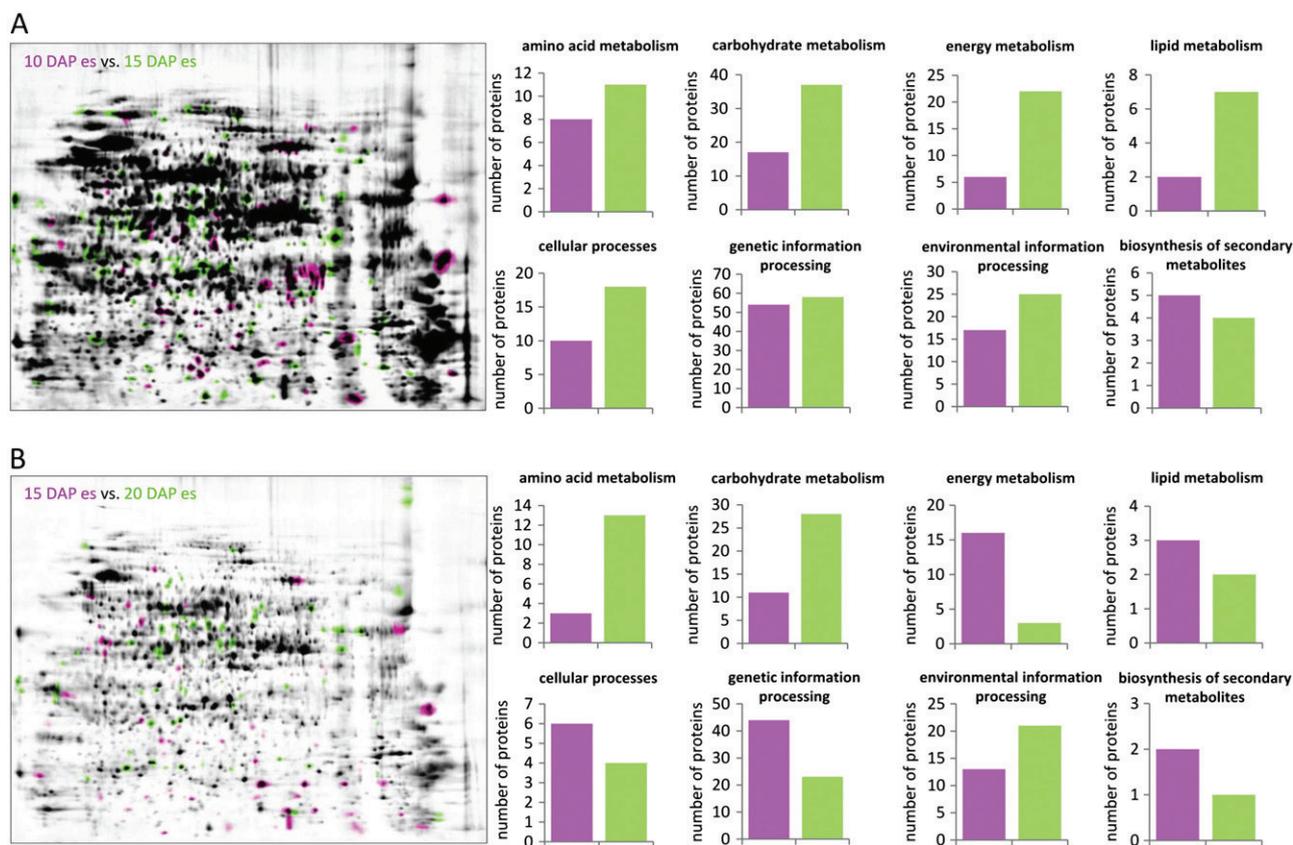

cell death [11]. Accordingly, metacaspase 7, a protein involved in programmed cell death, was detected in the course of our study.

#### (iv) Energy metabolism

Embryos of green seeds perform photosynthesis to support biosynthetic activity and to diminish oxygen shortage [58]. Several proteins involved in photosynthetic processes were found in the endosperm, including various isoforms of the RuBisCO subunits, PSII and PSI subunits, light harvesting proteins, subunits of the cytochrome  $b_6/f$  complex, chlorophyll a-b binding protein, ferredoxin NADP reductase, subunits of chloroplast ATP synthase and early light induced protein. Additionally, the oxygen evolving enhancer protein, which might promote oxygen production, was found at high abundance in the endosperm.

#### (v) Cellular processes

Several proteins involved in cell wall biogenesis were detected in the course of our study, including alpha-1,4-glucan-protein synthase, xyloglucan galactosyltransferase, UDP arabinopyranose mutase, UDP-glucose-6-dehydrogenase and fibrillin. Furthermore, an endoglucanase involved in cell wall degradation was identified. The endosperm includes cytoskeleton proteins such as tubulin, actin, and profilin to

**Fig. 6 – Changes in protein abundance during endosperm development. Three developmental stages of the *B. napus* endosperm were investigated (10, 15, 20 DAP) by 2D IEF/SDS PAGE and Delta2D analysis. To determine significant changes in spot volume, a Student's t-test ( $p$ -value  $\leq 0.05$ ) was applied on the basis of normalized relative spot volume. Changes in spot volume  $\geq 1.5$  were considered to represent true alterations. Protein spots of increased volume at 15 DAP (with respect to 10 DAP, A) and at 20 DAP (with respect to 15 DAP, B) are illustrated at the fused gel image of both groups in green, protein spots of reduced volume at 15 DAP (with respect to 10 DAP) and at 20 DAP (with respect to 15 DAP) in pink. The number of changed spots with respect to selected functional protein categories is given to the right of the gels (same color code).**

ensure vesicle and membrane transport activities. The identification of proteins related to membrane trafficking and protein transport processes such as glycolipid transfer protein, plastid lipid associated protein, patellin, clathrin adaptor complexes, dynamin, importin, GOLD family protein, Mov34/MPN/PAD-1 family protein, NSF attachment protein, TOC75-3, RAB GTPase, Ran binding protein and RAB GDP dissociation inhibitor indicates occurrence of regulated transport processes and membrane biogenesis in the endosperm tissue.

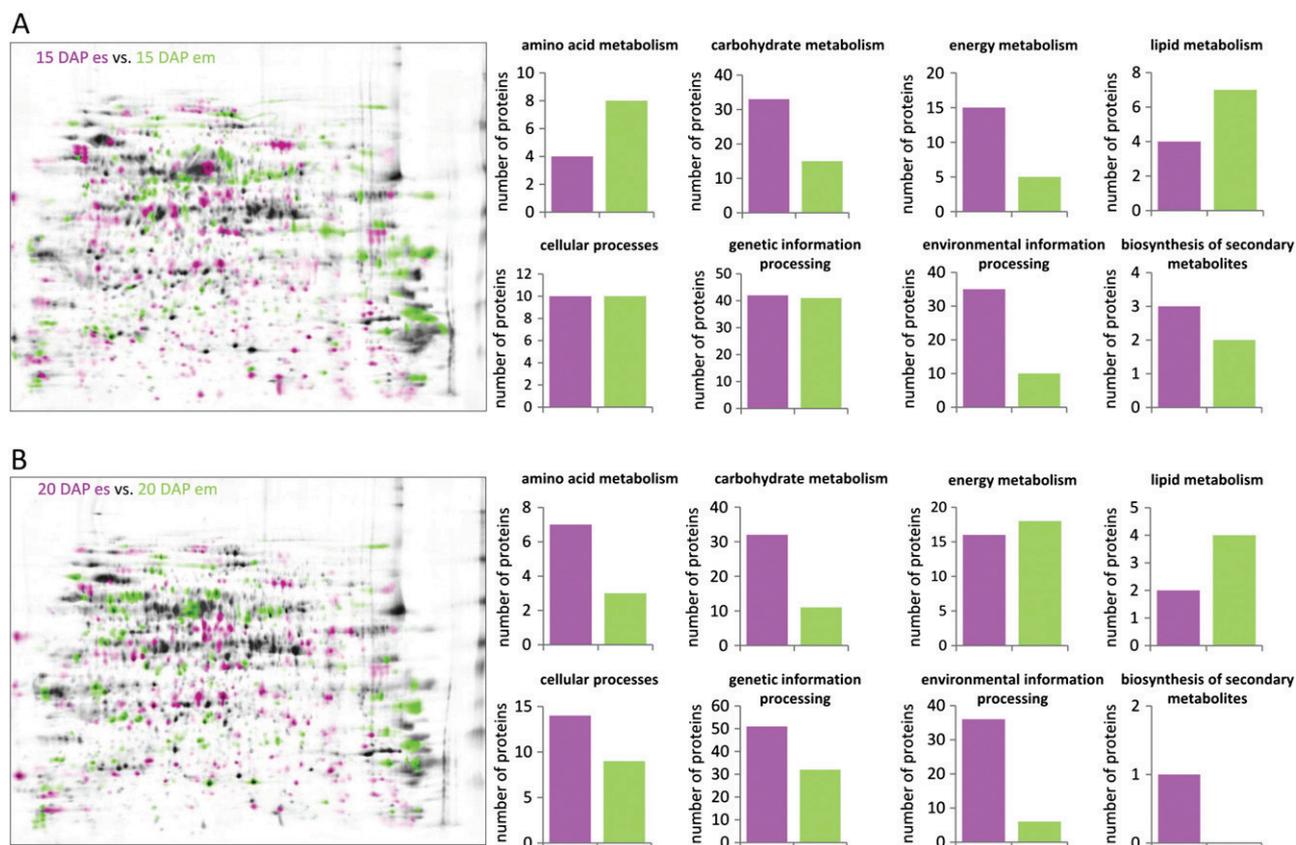

(vi) *Amino acid metabolism*

The endosperm is known to receive amino acids from the mother plant, to transiently store and deliver them toward the growing embryo [32]. We here identified a large set of proteins involved in (i) *alanine, aspartate and glutamate metabolism* (alanine aminotransferase, aspartate aminotransferase, glutamate dehydrogenase), (ii) *arginine metabolism* (acetylornithine deacetylase), (iii) *cysteine and methionine metabolism* (adenosylhomocysteinase, methionine synthase, S-adenosylmethionine synthase,

1,2-dihydroxy-3-keto-5-methylthiopentene dioxygenase, 5-methyltetrahydropteroyltriglutamate-homocysteine methyltransferase), (iv) *glycine, serine and threonine metabolism* (serine hydroxymethyltransferase, PLP-dependent transferase), (v) *lysine biosynthesis* (lysine decarboxylase, LL-diaminopimelate aminotransferase) and (vi) *valine, leucine and isoleucine metabolism* (3-isopropylmalate dehydrogenase, methylmalonate-semialdehyde dehydrogenase). These findings support the view that the endosperm is not only a (passive) port of transit for amino acids but possesses a pronounced amino acid metabolism, supporting its own demands and able to respond to embryo's requirements.

### 3.2. Developmental changes in the endosperm proteome in comparison to embryo

Comparative proteomics was employed to obtain insights into the dynamic changes of proteins during *B. napus* seed development. For this approach, two experimental lines were followed: (i) comparison of different

**Fig. 7 – Differences of endosperm and embryo proteomes.** Embryo and endosperm proteomes were investigated at 15 DAP (A) and at 20 DAP (B) by 2D IEF/SDS PAGE and Delta2D analysis. To determine significant differences in spot volume, a Student's t-test ( $p$ -value  $\leq 0.05$ ) was applied on the basis of normalized relative spot volume. Changes in spot volume  $\geq 1.5$  were considered to represent true alterations. Protein spots of increased volume in the endosperm (with respect to the embryo) are illustrated at the fused gel image of both groups in pink, protein spots of reduced volume in the endosperm (with respect to the embryo) in green. The number of changed spots with respect to selected functional protein categories is given to the right of the gels (same color code).

endosperm developmental stages and (ii) comparison of endosperm versus embryo. In a pre-experiment, seed development was systematically characterized by visual inspection to determine endosperm and embryo stages suitable for proteome analyses (Fig. 4). The embryo and also the endosperm of *B. napus* seeds are green during development. From 7 to 10 DAP the seed consists of

endospermal liquid, very thin endospermal cell layers, and a seed coat while the embryo is hardly visible by eye. At the beginning of the cotyledon stage (14 DAP) the embryo becomes visible. During further development the largely fluid endosperm is gradually replaced by the growing embryo. At 25 DAP the endosperm is no more visible and its development is terminated while the

**Table 1 – Number of spots with altered volumes and identified proteins within the comparisons (i)–(vi).**

Comparison	Days after pollination	Tissue	Number of spots with increased (↑) or decreased (↓) volume	Number of identified proteins
(i)	10 → 15	Endosperm	↑105	205
			↓71	147
(ii)	15 → 20	Endosperm	↑65	106
			↓61	112
(iii)	15 → 20	Embryo	↑41	80
			↓45	48
(iv)	20 → 25	Embryo	↑78	108
			↓68	113
(v)	15 → 15	Endosperm/embryo	↑351	182
			↓276	111
(vi)	20 → 20	Endosperm/embryo	↑271	194
			↓212	93

embryo is still expanding. Accompanied by the color transition of the seed coat from green to brown also the embryo changes its color. Reduction of green pigments starts at the radicle and then spreads to the inner and outer cotyledons. At late maturation, embryo growth stops and desiccation of the seed is initiated. Based on this developmental sequence, six different fractions were taken for further proteomic analyses: endosperm tissue at 10, 15 and 20 DAP and embryo tissue at 15, 20 and 25 DAP.

Total soluble proteins were extracted from the six selected stages and analyzed by comparative proteomics. The workflow was based on three gel replicates per fraction and Delta2D analyses (summarized in Fig. 5). Proteins of differential abundance within the compared fractions were identified using the reference map or MS analyses. While overall proteome architecture with respect to the molecular mass and pI profiles of proteins of the six compared fractions are largely unchanged (Supplementary Fig. 10), the protein composition within the fractions specifically differs. We carried out six comparisons:

- (i) Changes of the endosperm proteome at 15 DAP with respect to 10 DAP (Fig. 6, Supplementary Figs. 1, 2, Table 2)
- (ii) Changes of the endosperm proteome at 20 DAP with respect to 15 DAP (Fig. 6, Supplementary Figs. 1, 3, Table 3)
- (iii) Changes of the embryo proteome at 20 DAP with respect to 15 DAP (Supplementary Figs. 4, 5, 7, Supplementary Table 1).
- (iv) Changes of the embryo proteome at 25 DAP with respect to 20 DAP (Supplementary Figs. 4, 6, 7, Supplementary Table 1)
- (v) Differences between the endosperm and embryo proteomes at 15 DAP (Fig. 7A, Supplementary Fig. 8, Table 4)
- (vi) Differences between the endosperm and embryo proteomes at 20 DAP (Fig. 7B, Supplementary Fig. 9, Table 5)

Table 1 summarizes the number of spots which have reduced or increased volumes and the corresponding proteins identified by MS in the six comparisons (changes in abundance of  $\geq 1.5$  fold).

In the following sections, based on the six proteomic comparisons, developmental changes of processes taking place in both endosperm and embryo are discussed. Since many spots include more than one protein and since some proteins are present in more than one spot, quantitative regulation patterns for individual enzymes cannot be concluded from our experimental approach. However, tendencies for dynamic changes of functional processes are clearly visible (Figs. 6 and 7):

- (i) Changes of the endosperm proteome at 15 DAP with respect to 10 DAP: The number of proteins included in spots with altered volumes rather increases than decreases for most functional categories (Fig. 6A, Supplementary Figs. 1, 2, Table 2). Notably, proteins involved in energy metabolism, carbohydrate metabolism, amino acid and lipid metabolism increase. This underlines the rising metabolic activity (storage

metabolism) of endosperm and the fundamental role of endosperm in nutrient supply for the embryo at 15 DAP. Also, proteins involved in environmental information processing increase. In contrast, no clear tendency in up- or down-regulation of proteins involved in genetic information processing is visible at 15 DAP with respect to 10 DAP. The number of proteins involved in the biosynthesis of secondary metabolites decreases from 10 to 15 DAP.

- (ii) Changes of the endosperm proteome at 20 DAP with respect to 15 DAP: During development from 15 to 20 DAP, many processes in the endosperm significantly change. In contrast to the situation from 10 DAP to 15 DAP, further development of the endosperm until 20 DAP is accomplished with a relative reduction of proteins involved in energy metabolism (Fig. 6B, Supplementary Figs. 1, 3, Table 3). Interestingly, also lipid metabolism of the endosperm rather goes down from 15 to 20 DAP. In contrast, amino acid and carbohydrate metabolism as well as environmental information processing further increase from 15 to 20 DAP in the endosperm.
- (iii)/(iv) Changes of the embryo proteome at 20 DAP with respect to 15 DAP and at 25 DAP with respect to 20 DAP: Changes in processes during seed development clearly differ between the endosperm and the embryo (Supplementary Figs. 4–7, Supplementary Table 1). In the embryo, energy metabolism significantly increases up from 15 to 20 DAP. Also, lipid metabolism and biosynthesis of secondary metabolites are enhanced and even further increase from 20 to 25 DAP. Carbohydrate and amino acid metabolism first goes up from 15 to 20 DAP in the embryo but decreases from 20 to 25 DAP. As a consequence, metabolism is shifted at 25 DAP from carbohydrate/amino acid metabolism to lipid/secondary metabolism in the embryo. The latter might reflect the shift from transient starch synthesis to both starch degradation and oil storage [53].
- (v)/(vi) Differences between the endosperm and embryo proteomes at 15 DAP and at 20 DAP (Fig. 7A, B, Supplementary Figs. 8 and 9, Tables 4 and 5): If embryo and endosperm proteomes are directly compared at 15 and 20 DAP, respectively, fundamental differences are visible with respect to various cellular and metabolic processes: energy metabolism is clearly more pronounced in the endosperm than in the embryo at 15 DAP. This changes until 20 DAP when the embryo is fully competent in photosynthesis. At 15 and 20 DAP, environmental information processing rather takes place in the endosperm than in the embryo. This might underline the protective role of the endosperm for the embryo at both time points. Also carbohydrate metabolism is more pronounced in the endosperm at 15 as well as 20 DAP. In contrast, amino acid metabolism in the embryo at 15 DAP is prominent but decreases with respect to the endosperm until 15 DAP. Finally, lipid metabolism is especially pronounced in the embryo at 15 and 20 DAP.

As stated above, our experimental approach does not allow to quantify the changes in abundance for individual enzymes because most spots on our 2D gels include more than one protein. However, in some cases, quantitative changes are visible for individual proteins and in several other tendencies can be seen (see Supplementary discussion).

### 3.3. Concluding remarks

This study revealed for the first time the characteristics of the *B. napus* endosperm proteome, allowing to deduce dynamic changes in its metabolic and cellular processes. It became obvious that the metabolic architecture of endosperm comprises the entire set of central metabolic pathways. Its enzymatic machinery turns the endosperm into a self-sustaining, metabolically competent tissue, which of course receives major assimilates from the mother plant, but which is able to produce all or most of the needed metabolic intermediates by itself. It remains to be seen how this ability affects the assimilate supply/composition toward the developing embryo. The endosperm undergoes a unique developmental sequence from proliferation, growth and transient storage product accumulation toward programmed cell death. This developmental shift is clearly reflected in the proteome by the sequential appearance of proteins involved in energy metabolism, carbohydrate, amino acid and lipid metabolism. Notably, our analysis of the endosperm proteome also revealed a high number of proteins involved in redox balancing. It is tempting to speculate that a tight redox control in the endosperm is of highest significance, providing the embryo with a non-oxidizing environment. Such conditions were recently proposed to be key for germ cell fate and sexual reproduction [59]. Finally, proteome analysis indicated a high number of transcription factors and regulatory components in endosperm. It is very likely that their involvement in the various signaling cascades makes a fundamental contribution to coordinated seed development. A more targeted approach could help to identify their specific, individual contribution to growth control and eventually crop yield. As a next step, we plan absolute quantification of proteins involved in seed metabolism, e.g. by Selected Reaction Monitoring (SRM) mass spectrometry. This will allow to even deeper investigate the metabolic infrastructure of endosperm as well as its interplay with the developing embryo. In combination with metabolite profiling and isotope-based flux analysis, this will further improve our systems-level understanding of the *seed filling* process and provide rational strategies for bioengineering.

**Table 2 – Identification of proteins from spots with changed abundance in the endosperm between 10 DAP and 15 DAP. To determine significant changes in spot volume, a Student's t-test ( $p$ -value  $\leq 0.05$ ) was applied on the basis of normalized relative spot volume. Changes in spot volume  $\geq 1.5$  were considered to represent true alterations. Identification of proteins was carried out using the MASCOT search algorithm ([www.matrixscience.com](http://www.matrixscience.com)) against the (i) SwissProt ([www.uniprot.org](http://www.uniprot.org)), (ii) NCBInr ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)) and (iii) TAIR ([www.arabidopsis.org](http://www.arabidopsis.org), TAIR release 10) databases. Identified proteins were functionally classified according to the KEGG PATHWAY Database (<http://www.genome.jp/kegg/pathway.html>). The pathway categories were adjusted for seed metabolism by adding four functional groups: (i) storage, (ii) defense, (iii) desiccation and (iv) detoxification.**

<sup>a</sup> Spot number in accordance with Supplementary Fig. 2.

<sup>b</sup> Developmental stage of endosperm (es) 10 and 15 DAP.

<sup>c</sup> Regulation of spots, spot volume at least 1.5 fold increased in the corresponding developmental stage.

<sup>d</sup> Accession numbers as given by SwissProt (<http://www.uniprot.org>), NCBI nr (<http://www.ncbi.nlm.nih.gov/protein>) and TAIR (<http://www.Arabidopsis.org/>).

<sup>e</sup> Calculated molecular masses of the identified proteins as deduced from the corresponding genes.

<sup>f</sup> Calculated isoelectric point of the identified proteins as deduced from the corresponding genes.

<sup>g</sup> Probability score for the protein identifications based on MS/MS analysis and MASCOT search.

<sup>h</sup> Number of unique matching peptides.

<sup>i</sup> Sequence coverage of a protein by identified peptides.

**Table 3 – Identification of proteins from spots with changed abundance in the endosperm between 15 DAP and 20 DAP. To determine significant changes in spot volume, a Student's t-test (p-value  $\leq$  0.05) was applied on the basis of normalized relative spot volume. Changes in spot volume  $\geq$  1.5 were considered to represent true alterations. Identification of proteins was carried out using the MASCOT search algorithm ([www.matrixscience.com](http://www.matrixscience.com)) against the (i) SwissProt ([www.uniprot.org](http://www.uniprot.org)), (ii) NCBI nr ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)) and (iii) TAIR ([www.arabidopsis.org](http://www.arabidopsis.org), TAIR release 10) databases. Identified proteins were functionally classified according to the KEGG PATHWAY Database (<http://www.genome.jp/kegg/pathway.html>). The pathway categories were adjusted for seed metabolism by adding four functional groups: (i) storage, (ii) defense, (iii) desiccation and (iv) detoxification.**

<sup>a</sup> Spot number in accordance with Supplementary Fig. 3.

<sup>b</sup> Developmental stage of endosperm (es) 15 and 20 DAP.

<sup>c</sup> Regulation of spots, spot volume at least 1.5 fold increased in the corresponding developmental stage.

<sup>d</sup> Accession numbers as given by SwissProt (<http://www.uniprot.org>), NCBIInr (<http://www.ncbi.nlm.nih.gov/protein>) and TAIR (<http://www.Arabidopsis.org/>).

<sup>e</sup> Calculated molecular masses of the identified proteins as deduced from the corresponding genes.

<sup>f</sup> Calculated isoelectric point of the identified proteins as deduced from the corresponding genes.

<sup>g</sup> Probability score for the protein identifications based on MS/MS analysis and MASCOT search.

<sup>h</sup> Number of unique matching peptides.

<sup>i</sup> Sequence coverage of a protein by identified peptides.

**Table 4 – Identification of proteins from spots with changed abundance in the endosperm compared to the embryo at 15 DAP. To determine significant changes in spot volume, a Student's t-test ( $p$ -value  $\leq 0.05$ ) was applied on the basis of normalized relative spot volume. Changes in spot volume  $\geq 1.5$  were considered to represent true alterations. Identification of proteins was carried out using the MASCOT search algorithm ([www.matrixscience.com](http://www.matrixscience.com)) against the (i) SwissProt ([www.uniprot.org](http://www.uniprot.org)), (ii) NCBI nr ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)) and (iii) TAIR ([www.arabidopsis.org](http://www.arabidopsis.org), TAIR release 10) databases. Identified proteins were functionally classified according to the KEGG PATHWAY Database (<http://www.genome.jp/kegg/pathway.html>). The pathway categories were adjusted for seed metabolism by adding four functional groups: (i) storage, (ii) defense, (iii) desiccation and (iv) detoxification.**

<sup>a</sup> Spots in accordance with Supplementary Fig. 8.

<sup>b</sup> Developmental stage of endosperm (es) and embryo (em) at 15 DAP.

<sup>c</sup> Regulation of spots, spot volume at least 1.5 fold increased in the corresponding developmental stage.

<sup>d</sup> Accession numbers as given by SwissProt (<http://www.uniprot.org>), NCBItr (<http://www.ncbi.nlm.nih.gov/protein>) and TAIR (<http://www.Arabidopsis.org/>).

<sup>e</sup> Calculated molecular masses of the identified proteins as deduced from the corresponding genes.

<sup>f</sup> Calculated isoelectric point of the identified proteins as deduced from the corresponding genes.

<sup>g</sup> Probability score for the protein identifications based on MS/MS analysis and MASCOT search.

<sup>h</sup> Number of unique matching peptides.

<sup>i</sup> Sequence coverage of a protein by identified peptides.

**Table 5 – Identification of proteins from spots with changed abundance in the endosperm compared to the embryo at 20 DAP. To determine significant changes in spot volume, a Student's t-test (p-value  $\geq 0.05$ ) was applied on the basis of normalized relative spot volume. Changes in spot volume  $\geq 1.5$  were considered to represent true alterations. Identification of proteins was carried out using the MASCOT search algorithm ([www.matrixscience.com](http://www.matrixscience.com)) against the (i) SwissProt ([www.uniprot.org](http://www.uniprot.org)), (ii) NCBI nr ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)) and (iii) TAIR ([www.arabidopsis.org](http://www.arabidopsis.org), TAIR release 10) databases. Identified proteins were functionally classified according to the KEGG PATHWAY Database (<http://www.genome.jp/kegg/pathway.html>). The pathway categories were adjusted for seed metabolism by adding four functional groups: (i) storage, (ii) defense, (iii) desiccation and (iv) detoxification.**

**Background:** Cruciferin represents the most abundant protein in *Brassica napus* seeds where its efficient storage is essential under minimized space conditions.

**Results:** The cruciferin complex has an octameric barrel-like structure of ~420 kDa.

**Conclusion:** The barrel-like structure represents a compact building block optimized for maximal storage of amino acids.

**Significance:** Novel insights into structure and packing of seed storage proteins.

Globulins are an important group of seed storage proteins in dicotyledonous plants. They are synthesized during seed development, assembled into very compact protein complexes, and finally stored in protein storage vacuoles (PSVs). Here, we report a proteomic investigation on the native composition and structure of cruciferin, the 12 S globulin of *Brassica napus*. PSVs were directly purified from mature seeds by differential centrifugations. Upon analyses by blue native (BN) PAGE, two major types of cruciferin complexes of ~300–390 kDa and of ~470 kDa are resolved. Analyses by two-dimensional BN/SDS-PAGE revealed that both types of complexes are composed of several copies of the cruciferin  $\alpha$  and  $\beta$  polypeptide chains, which are present in various isoforms. Protein analyses by two-dimensional isoelectric focusing (IEF)/SDS-PAGE not only revealed different  $\alpha$  and  $\beta$  isoforms but also several further versions of the two polypeptide chains that most likely differ with respect to posttranslational modifications. Overall, more than 30 distinct forms of cruciferin were identified by mass spectrometry. To obtain insights into the structure of the cruciferin holocomplex, a native PSV fraction was analyzed by single particle electron microscopy. More than 20,000 images were collected, classified, and used for the calculation of detailed projection maps of the complex. In contrast to previous reports on globulin structure in other plant species, the cruciferin complex of *Brassica napus* has an octameric barrel-like structure, which represents a very compact building block optimized for maximal storage of amino acids within minimal space.

Seed storage proteins accumulate during the seed filling process and serve as a source of nitrogen and amino acids for the germinating embryo. In dicotyledonous plants, e.g. sunflower, soybean, *Arabidopsis*, and rapeseed, the most abundant storage proteins are the 2 S albumins and 7 S and 12 S globulins, the latter ones representing the phylogenetically most widely distributed group of storage proteins. Mature 12 S globulins consist of two polypeptide chains, which are covalently linked by a disulfide bond. Both chains stem from the same precursor molecule, which is co-translationally synthesized into the rough endoplasmic reticulum. During import, the endoplasmic reticulum signal peptide is cleaved off and a disulfide bond is formed between the N- and C-terminal parts of the polypeptide chain (1, 2). These proglobulins are then assembled into trimers (3), transported through the Golgi apparatus, and finally stored as mature hexamers in protein storage vacuoles (PSVs).<sup>4</sup> In this process, at least a second cleavage of the proglobulin occurs, which forms the mature protein with  $\alpha$  and  $\beta$  polypeptide chains. The latter step is a prerequisite for hexamer assembly (4, 5). The site of this second cleavage is between an asparagine and glycine residue and both amino acids are highly conserved among the group of the 12 S globulins (5, 6). Several proteases, so-called vacuolar processing enzymes, which belong to a novel family of cysteine proteinases, are responsible for this second cleavage of the monomers (7). Recently, it was shown that vacuolar processing enzymes as well as the corresponding storage proteins are sorted in the Golgi apparatus simultaneously in two different types of vesicles. Subsequently, these vesicles fuse to form a prevacuolar compartment, the multivesicular body in which the proteolytic process takes place (8, 9). Later, multivesicular bodies fuse into a PSV. Most members of the 12 S globulins are believed to undergo these two events of posttranslational cleavage (4, 6, 7), and the resulting polypeptide chains are referred to as the  $\alpha$  polypeptide chain (the original N-terminal

Native Structure and Composition of Cruciferin in *B. napus*

part of the precursor protein) and the  $\beta$  polypeptide chain (the original C-terminal part).

Also in *Brassica napus*, a 12 S globulin, cruciferin, is the major storage protein and accounts for ~60% of the total seed protein (10). Five different *B. napus* cruciferins belong to three different families, which are listed in the reviewed UniProtKB database. The P1 family contains only one protein, CRU1, with a sequence length of 509 amino acids (AA) ( $\alpha_1 = 296$  AA and  $\beta_1 = 190$  AA). In contrast, the P2 family contains three proteins: BnC1 with a sequence length of 490 AA ( $\alpha_2 = 277$  AA and  $\beta_2 = 190$  AA); BnC2 with a sequence length of 496 AA ( $\alpha_3 = 283$  AA and  $\beta_3 = 190$  AA) and CRU2/3 with a sequence length of 488 AA ( $\alpha_{2/3} = 275$  and  $\beta_{2/3} = 190$  AA). The P3 family contains one protein, CRU4 with a sequence length of 465 AA ( $\alpha_4 = 254$  AA and  $\beta_4 = 189$  AA). Similar to other 12S globulins, all cruciferin family members are secreted into the endoplasmic reticulum, and all exhibit the typical conserved 12S globulin cleavage site between asparagine and glycine. They are thought to be transported as trimers via the Golgi apparatus and stored as hexamers in PSVs (11–15).

Currently, little is known about the structure and organization of *B. napus* cruciferin within the PSV, although this most likely is important for ensuring efficient use of storage space in developing seeds. The first reports on the quaternary structure of a 12S globulin were given by Badley *et al.* (16) in 1975. Using electron microscopy, it was shown that the soybean 12S globulin glycinin extracted from soy flour is composed of two hexagonal rings with alternating  $\alpha$  and  $\beta$  polypeptide chains. This dodecameric model was also supported by Marcone *et al.* (17) for amaranth globulin isolated from defatted flour. However, for rapeseed and sunflower globulin a triangular antiprism of six subunits was suggested (18). In subsequent x-ray crystallographic studies, soybean proglycinin and rapeseed procruciferin overexpressed in *Escherichia coli* were reported to exhibit triangular patterns (19–21). The crystal structure of a mature soybean glycinin extracted from a mutant soybean cultivar indicates a hexameric particle formed by two face-to-face stacking trimers (22). Two conclusions can be drawn from these results: (i) quaternary structures of 12S globulins may vary between species, and (ii) the quaternary structure of 12S globulins also can differ for the same species, depending on the expression system used for globulin biosynthesis (*e.g.* soybean *versus E. coli*). Consequently, detailed structural information of native cruciferin is best obtained directly from the plant species of interest without the use of heterologous expression systems.

In this study, *B. napus* cruciferin complexes were directly isolated from mature seeds under native conditions. The resulting fractions were highly enriched with cruciferin. Purified proteins were used for investigations by various gel electrophoresis systems, mass spectrometry and single particle EM. A large variation with respect to isoelectric points and molecular mass was observed for the cruciferin  $\alpha$  and  $\beta$  polypeptide chains. In contrast to 12S globulin complexes from other plant species, the cruciferin complex exhibits a unique octameric structure that allows packaging of the amino acids under most space-saving conditions.

## EXPERIMENTAL PROCEDURES

**Cultivation of *B. napus***—*B. napus* plants were cultivated in growth chambers under the following conditions: 16-h light (16 klux) at 22 °C, 8-h dark at 18 °C with a relative humidity of 55%. Seeds were harvested 53 to 60 days after pollination (DAP) and directly used for the isolation of PSVs.

**Isolation of Protein Storage Vacuoles**—Native proteins from PSVs were isolated as described previously (23). All steps were carried out at 4 °C or on ice. 14 g of mature seeds were harvested and directly homogenized in 100 ml of glycerol (100% (v/v)) using a mortar and a pestle. The homogenate was filtered through one layer of Miracloth (20–25  $\mu$ m, Calbiochem) and centrifuged for 10 min at 1100  $\times g$ . To collect PSVs, the supernatant was centrifuged for 20 min at 41,000  $\times g$ . The pellet was again resuspended in glycerol (30 ml, 100% (v/v)) and centrifuged for 20 min at 41,000  $\times g$ . This pellet contained the PSV fraction and was further resuspended in 10 ml of TE buffer (1 mM EDTA, 5 mM Tris-HCl, pH 8.5) to disrupt the PSV and loaded onto a discontinuous sucrose step gradient (30, 45, and 68% (w/v) sucrose in TE buffer) for 2 h at 78,000  $\times g$ . The fraction above the 30% sucrose layer represents the vacuolar matrix containing the storage proteins and was directly used or frozen in liquid nitrogen and stored at –80 °C.

**Gel Electrophoresis Procedures**—Proteins were analyzed by one-dimensional blue native polyacrylamide gel electrophoresis (BN PAGE) and by two-dimensional BN/SDS-PAGE using 100  $\mu$ l of the frozen PSV matrix fraction supplemented with 5  $\mu$ l of “blue loading buffer” (5% (w/v) Coomassie Blue in 750 mM aminocaproic acid) according to the protocol outlined in Wittig *et al.* (24). Mitochondria from *Arabidopsis thaliana* were prepared as outlined in Sunderhaus *et al.* (25) and solubilized by 5 g/g digitonin. One-dimensional SDS-PAGE was carried out as described by Schagger and von Jagow (26) using 30  $\mu$ l of the frozen PSV matrix fraction. For two-dimensional isoelectric focusing/SDS-PAGE (IEF/SDS-PAGE), 50  $\mu$ l of the PSV fraction were mixed with 300  $\mu$ l of resuspension buffer (8 M urea, 2 M thiourea, 50 mM DTT, 2% CHAPS (w/v), 5% IPG buffer 3–11 nl (v/v), 12  $\mu$ l/ml DeStreak reagent, bromphenol blue) and directly applied into a strip holder. Isoelectric focusing was carried out with the Ettan IPGphor 3 apparatus (GE Healthcare) using 3–11 nl of Immobiline DryStrip gels (18 cm). Rehydration took place at 30 V for 12 h and focusing during 4 steps at 500 V (1 h), 500–1000 V (1 h), 1000–8000 V (3 h), and 8000 V (6 h). Afterward, strips were equilibrated for 15 min in equilibration solution (6 M urea, 30% glycerol (87%, v/v), 2% SDS, 50 mM Tris-HCl, pH 8.8, bromphenol blue) with (i) 1% DTT (w/v) and (ii) 2.5% iodacetamide (w/v). IPG strips were finally transferred horizontally onto a 16.5% tricine gel, and electrophoresis was carried out for 20 h at 35 mA/mm gel layer.

**Gel Staining Procedures**—All polyacrylamide gels were stained with Coomassie colloidal (27, 28).

**Generation of Antibodies against Cruciferin**—Two different polyclonal antibodies directed against peptides of the  $\alpha$  or  $\beta$  polypeptide chains of *B. napus* cruciferin were generated (Eurogentec S.A. Antisera Production, Seraing, Belgium). For details, see supplemental Fig. 1.

## Native Structure and Composition of Cruciferin in *B. napus*

**Western Blotting**—Proteins separated on polyacrylamide gels were blotted onto nitrocellulose membranes for antibody staining using the Trans Blot Cell from Bio-Rad. Blotting was carried out as described in Kruff *et al.* (29). Immunostainings were performed using the VectaStain ABC kit (Vector Laboratories, Burlingame, CA).

**MS Analyses**—Tryptic digestion of proteins and peptide extraction were carried out as published in Sunderhaus *et al.* (25). MS analyses were performed using an EASY-nLC-system (Proxeon) coupled to a MicroTOF-Q-II mass spectrometer (Bruker Daltonics). Identification of proteins was carried out using the MASCOT search algorithm against (i) SwissProt (ii) NCBI non-redundant protein database and (iii) The *Arabidopsis* Information Resource (Tair release 9).

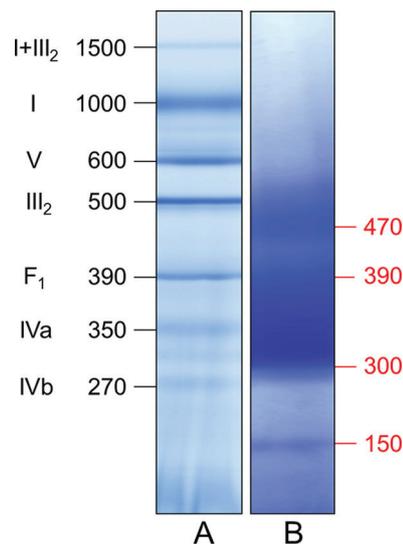

**Electron Microscopy and Image Analyses**—Fractions containing cruciferin were applied to carbon-coated copper grids and negatively stained with 2% uranyl acetate. Electron microscopy was performed on a Philips CM120 electron microscope. Data were collected with a 4K slow-scan CCD camera (Gatan) at a magnification of 130,000 with a pixel size (after binning the images) of 0.23 nm at the specimen level. Single particle analysis was performed with the Groningen Image Processing (GRIP) software package on a CPU cluster as outlined by Dudkina *et al.* (30). The three-dimensional model of cruciferin was created with a Blender three-dimensional creation suite. X-ray structure of procruciferin from *B. napus* (Protein Data Bank code 3KGL (20)) was used for the superimposing on projection maps of cruciferin. The octamer of cruciferin was generated from the hexameric x-ray structure of procruciferin maintaining monomer-monomer interfaces by using the Chimera program from the University of California, San Francisco (31).

## RESULTS

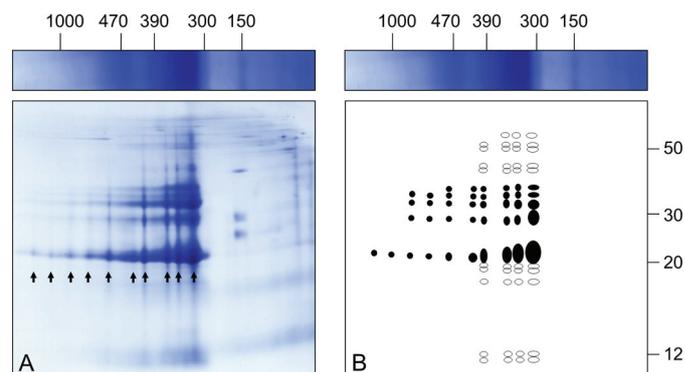

PSVs were isolated from freshly harvested seeds at 53 to 60 DAP under most gentle conditions using the glycerol protocol published by Jiang *et al.* (23). The total protein fraction was directly extracted from PSVs.

**Characterization of Cruciferin Complexes from *B. napus* Storage Vacuoles**—BN PAGE was originally developed for the characterization of native mitochondrial protein complexes but also proved to be a very suitable procedure for the investigation of protein complexes from other cellular compartments (24). To characterize the protein composition of the PSVs, their soluble fraction was directly supplemented with Coomassie blue and subsequently loaded onto a one-dimensional BN gel. As a control and molecular mass standard, respiratory protein complexes of *A. thaliana* mitochondria were solubilized by 5 g/g digitonin and separated on the same gel (Fig. 1). Three bands are visible in the lane of the PSV fraction: a central broad band sharply confined at its lower border at 300 kDa with a more diffuse upper border at ~390 kDa is flanked by two bands of lower abundances at ~150 and 470 kDa. Judging from the molecular masses of the bands, it can be expected that they represent multisubunit protein complexes.

To investigate the subunit compositions of the PSV protein complexes, two-dimensional BN/SDS-PAGE was carried out for separating the subunits of the resolved complexes (Fig. 2A). Under the denaturing conditions of the second gel dimension,

**FIGURE 1. Separation of soluble proteins from PSVs by BN PAGE indicates presence of three major classes of protein complexes of 150, 300–390, and 470 kDa.** The proteins of storage vacuoles of *B. napus* (lane B) and of a mitochondrial fraction of *A. thaliana* (molecular mass standard; lane A) were separated on a native gradient gel according to molecular mass. Molecular masses are given in kDa. Designations of *A. thaliana* mitochondrial protein complexes are given as follows: *I+III<sub>2</sub>*, supercomplex containing NADH dehydrogenase and dimeric cytochrome *c* reductase; *I*, NADH dehydrogenase; *V*, *F<sub>0</sub>F<sub>1</sub>* ATP synthase; *III<sub>2</sub>*, dimeric cytochrome *c* reductase; *F<sub>1</sub>*, *F<sub>1</sub>* part of the ATP synthase; *IVa* and *IVb*, larger and smaller form of cytochrome *c* oxidase.

**FIGURE 2. Separation of proteins isolated from PSVs by two-dimensional BN/SDS-PAGE (A) suggests specified associations of cruciferin.** Arrows indicate the occurrence of 10 defined cruciferin complexes with a maximum of 15 different protein species (given on the scheme in B). Highly abundant subforms are indicated in filled circles, less abundant subforms are in open circles. Molecular masses are given in kDa above and to the right of the gel.

the smaller 150-kDa complex dissociated into three subunits of ~40, 25, and 20 kDa. The two larger complexes dissociated into ~15 different subunits of 60 to 12 kDa. The protein patterns of both bands indicate that the two complexes have the same composition but differ in subunit stoichiometry. In contrast to the one-dimensional BN PAGE, even larger forms of this complex are visible on the two-dimensional gel, which is schematically summarized in Fig. 2B.

To verify that separated fractions contain cruciferin, peptide-specific antibodies were generated against the  $\alpha$  and  $\beta$  polypeptide chain of the protein (see supplemental Fig. 1). Two-dimensional BN/SDS gels were then blotted onto nitrocellulose membranes and incubated with antibodies directed against both chains (Fig. 3).

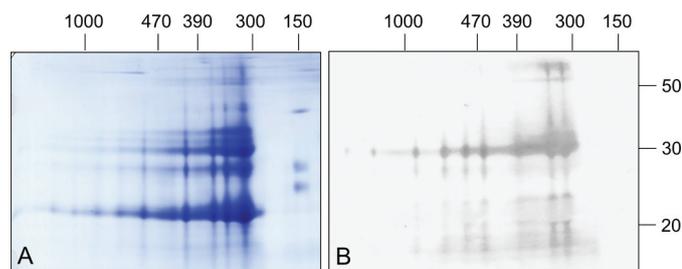

Native Structure and Composition of Cruciferin in *B. napus*

FIGURE 3. Immunoblotting analyses of a *B. napus* PSV fraction separated by two-dimensional BN/SDS-PAGE reveals high enrichment of cruciferin. Gels were either stained by Coomassie colloidal (A) or blotted onto nitrocellulose (B). Western blots were incubated with antibodies directed against the  $\alpha$  chain of cruciferin. Molecular masses of standard proteins are shown above and to the right of the gel (in kDa).

The obtained results illustrate the purity of the PSV fraction. A strong signal is present in the 30-kDa range, representing  $\alpha$  polypeptide chains from the different cruciferin families. Additionally, a strong signal is visible in the 55-kDa range indicating that few cruciferins still have an intact disulfide bond between both polypeptide chains after the  $\beta$ -mercaptoethanol treatment preceding the second dimension. Some weaker signals in the molecular mass range below 20 kDa most likely represent  $\alpha$  polypeptide chain breakdown products. Blots developed with antibodies against the  $\beta$  polypeptide chain of cruciferin show a strong signal in the 20 to 25 kDa range as well as in the 60 kDa range (data not shown). The two-dimensional gel shows that the broad band observed in the one-dimensional gel is actually composed of several individual bands and that cruciferin is present in all those bands, also in the 470-kDa band. Additionally, cruciferin at least partially occurs in larger forms up to 1500 kDa on one-dimensional BN gels but does not form part of the 150-kDa complex.

**Analyses of Cruciferin  $\alpha$  and  $\beta$  Polypeptide Chains at Reducing/Non-reducing Conditions**—To investigate the size of the monomeric cruciferin complex as well as its  $\alpha$  and  $\beta$  polypeptide chains, cruciferin isolated from PSVs was dissolved in either denaturing buffer containing DTT to reduce the disulfide bond between the N and the C terminus or in buffer without DTT to keep the protein in its native monomeric form. Fractions were separated using one-dimensional SDS gels and blotted onto nitrocellulose membranes, which were incubated with antibodies against either the  $\alpha$  or the  $\beta$  chain (Fig. 4).

Under denaturing conditions, antibodies directed against the  $\alpha$  polypeptide chain produced a strong signal visible in the 30-kDa range. Some additional but much weaker signals are observable in the range of 27 and 33 kDa and in the low molecular mass range between 14 and 20 kDa. No signals could be detected above 35 kDa, indicating that all cruciferin is cleaved into  $\alpha$  and  $\beta$  polypeptide chains by this treatment. In addition, incubation with antibodies directed against the  $\beta$  polypeptide chain produced a strong signal at 18 to 20 kDa as well as some minor bands in the range of 30–35 and at  $\sim$ 50 kDa (Fig. 4A). Under non-reducing conditions both antibodies gave the same signals in the 27–33 kDa and 18–20 kDa range, respectively, but with notably reduced intensities. Additionally, a number of new signals are visible in the range of  $\sim$ 52 kDa (Fig. 4B). Because these proteins are detected by the antibodies directed

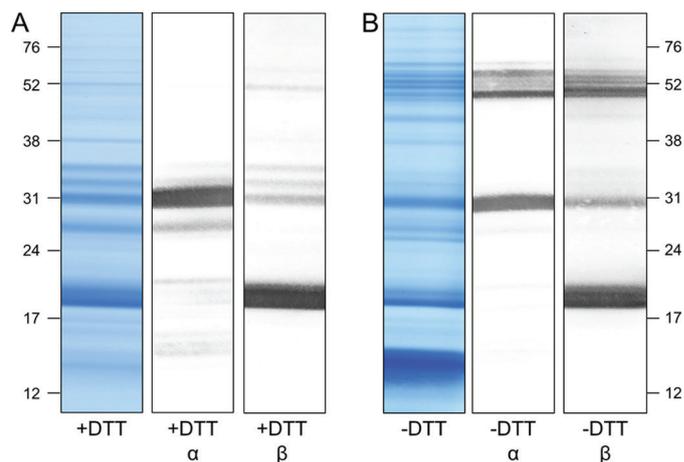

FIGURE 4. Immunoblotting analyses of a *B. napus* PSV fraction separated by one-dimensional SDS-PAGE reveals cruciferin complexes of  $\sim$ 48 to 58 kDa under non-reducing conditions. PSV fractions were separated under reducing conditions (A; +DTT) and non-reducing conditions (B; -DTT). Gels were either stained Coomassie colloidal or blotted onto nitrocellulose membranes and incubated with antibodies directed against the  $\alpha$  or the  $\beta$  chains of cruciferin as indicated. Molecular masses of standard proteins are shown to the right and to the left in kDa.

against the  $\alpha$  and the  $\beta$  polypeptide chains, these bands most likely represent cruciferins with intact disulfide bonds.

Because isoforms of cruciferin precursor proteins as well as their respective  $\alpha$  and  $\beta$  polypeptide chains cannot be separated on one-dimensional SDS gels due to similar molecular masses, the PSV fraction was analyzed by two-dimensional IEF/SDS-PAGE (Fig. 5). IEF is often capable of separating proteins with the same or similar molecular masses due to different occurrences of ionizable amino acids within isoforms.

As shown in Fig. 5 and by Western blotting (data not shown),  $\alpha$  polypeptide chains are separated in a range between 27 and 36 kDa and isoelectric points between 6.7 and 8.8 (red box). The corresponding  $\beta$  polypeptide chains are separated in a range between 19 and 21 kDa and isoelectric points between 5.9 and 9.5 (green box).

For assigning cruciferin polypeptide chains from the three individual cruciferin families to each detected spot/band on our one-dimensional BN (Fig. 1), two-dimensional BN/SDS (Fig. 3), one-dimensional SDS (Fig. 4), and two-dimensional IEF/SDS (Fig. 5) gels, protein identifications by mass spectrometry were carried out. A total number of 95 spots, representing the most abundant proteins, were picked from the four gel systems and analyzed by LC-ESI-Q-TOF-MS/MS (supplemental Fig. 2 and supplemental Table 1). Members of all five cruciferin families were detected as well as the 2 S storage protein Napin. The latter one is also known to accumulate during the seed filling process in *B. napus* PSVs. Furthermore, five proteins were identified, which do not belong to the family of storage proteins.

Altogether, mass spectrometry enabled the assignment of spots on two-dimensional IEF/SDS gels to distinct cruciferin families and polypeptide chains (Fig. 6). With respect to  $\alpha$  polypeptide chains, four spots in the range of 34-kDa spots were identified as  $\alpha$ CRU1 (P1); another four spots in the range of 32 kDa were assigned to  $\alpha$ BnC1,  $\alpha$ BnC2, and  $\alpha$ CRU2/3 (P2); and two spots in the range of 27 kDa represent  $\alpha$ CRU4 (P3). All six

FIGURE 5. Resolving a PSV fraction according to isoelectric point and molecular mass reveals existence of cruciferin  $\alpha$  chains in a pH range from 6.7 to 8.8 (red box) and  $\beta$ -chains in a pH range from 5.9 to 9.5 (green box). Molecular masses of standard proteins as well as the pI range are given on the right and above the gel, respectively.

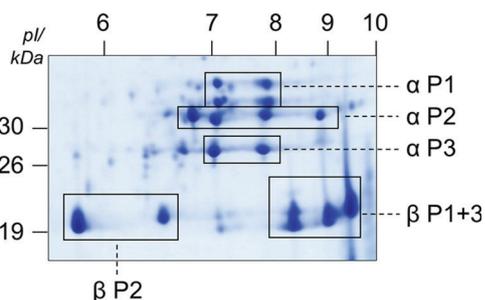

FIGURE 6. Analyses of cruciferin subunits by LC-MS/MS allows assigning clusters of spots on two-dimensional IEF/SDS gels to the three distinct cruciferin families. Names of families and polypeptide chain attribution are given to the right and below the gel. Molecular masses and pIs are given to the left and above the gel, respectively. P1, family 1 containing cruciferin Cru 1; P2, family 2 containing cruciferin BnC1, BnC2, and Cru 2/3; P3, family 3 containing cruciferin Cru 4.

spots in the range of 19 to 21 kDa were distinguishable exclusively by their isoelectric points, and they all represent  $\beta$  polypeptide chains. Four spots exhibiting isoelectric points of  $\sim 8$  to 9.5 were identified as  $\beta$ CRU1 and  $\beta$ CRU4 (P1 and P3), and two spots exhibiting isoelectric points from  $\sim 5.8$  to 6.8 were assigned to  $\beta$ BnC1,  $\beta$ BnC2, and  $\beta$ CRU2/3 (P2).

*The Cruciferins of Rapeseed Are Phosphorylated*—Phosphorylation of cruciferins was investigated using antibodies directed against phosphoserine, phosphothreonine, and phosphotyrosine. For this approach, storage vacuole protein fractions were separated by two-dimensional IEF/SDS-PAGE and blotted onto filter membranes (Fig. 7). Several cruciferin forms belonging to both the  $\alpha$  and the  $\beta$  chains are recognized by all three sera. Overall, the  $\alpha$  chain of cruciferin reacts stronger with the sera than the  $\beta$  chain. The strongest immune signals were obtained with the serum directed against phosphoserine (Fig. 7D).

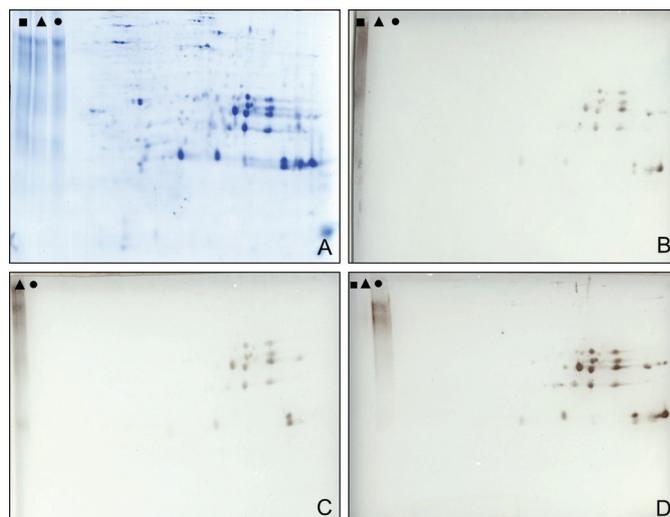

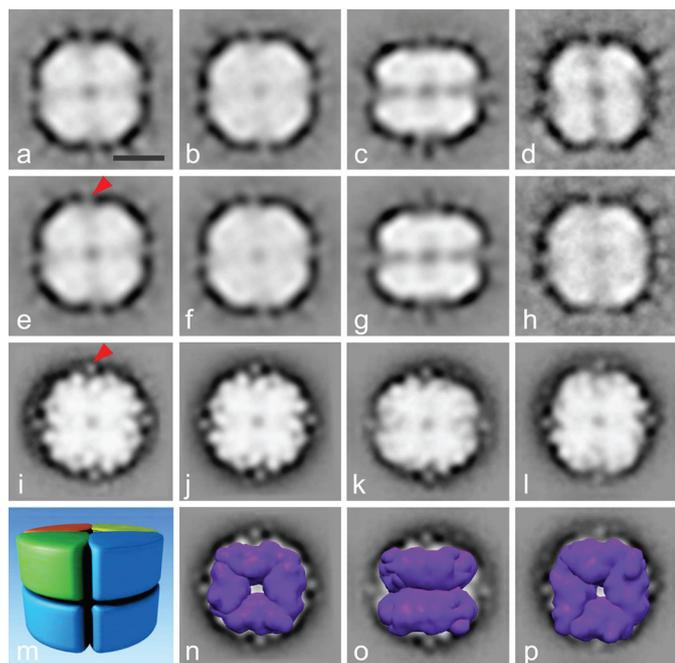

FIGURE 7. Immunological analysis of cruciferin phosphorylation. Protein storage vacuole fractions were resolved by two-dimensional IEF/SDS-PAGE and blotted onto membranes, and blots were developed using antibodies directed against three different phosphorylation sites. As a control, phosphorylated BSA (phosphorylated at tyrosine (▲); phosphorylated at threonine (●); phosphorylated at serine (■)) was separated within the same gel. A, Coomassie-stained reference gel. B, immunoblot developed with an IgG directed against phosphorylated tyrosine; C, immunoblot developed with an IgG directed against phosphorylated threonine; D, immunoblot developed with an IgG directed against phosphorylated serine. Note that the phosphotyrosine-BSA control on C is not indicated because it partially was beyond the limit of the blot. However, the specificity of the IgG was verified by independent experiments (not shown).

*Structure of the Native Cruciferin Storage Form in Mature PSVs*—For a structural analysis of the native cruciferin oligomers, PSV fractions purified from developing (53 DAP) or mature seeds (60 DAP) were examined and analyzed by single particle EM (Fig. 8). Altogether, 23,000 protein projections were analyzed to obtain final averages at  $\sim 20$  Å resolution after several iterations of alignment and classification. As can be seen from class averages, the majority of molecules appeared to be oriented in a top or bottom view positions (Fig. 8, a, b, d, e, f, h, i, j, and l), whereas only a smaller group of projections represented side views (Fig. 8, c, g, and k). The top and bottom views clearly demonstrate a 4-fold symmetry. By combining the information obtained on the top and side views, it can be concluded that the structure is composed of two layers, each consisting of four identical subunits in a tetrameric configuration enclosing a pore in the center of the complex. A groove divides the side-view projection into two halves, each of which appears to be mirror the other one in the projection. This indicates that the two sets of tetramers are facing each other in antiparallel positions.

From the single particle EM data shown in Fig. 8, we generated a model of the cruciferin storage complex (Fig. 8m). It is composed of eight subunits arranged in an octameric configuration rather than the hexamer, which was proposed by other studies for globulins from other organisms (11–15, 20, 22). From the dimensions observed in the projection maps, we estimated the mass of the octamer to be  $\sim 420$  kDa. Estimation was done by using a formula for the cylinder-shaped complex as  $m = \Pi R^2 h / \rho$ , where  $m$  is the mass of the protein,  $R$  and  $h$  are the radius and the height of the cylinder, and  $\rho$  is the average pro-

Native Structure and Composition of Cruciferin in *B. napus*

**FIGURE 8. Structural analyses of the cruciferin complex by single particle electron microscopy.** Top view (a, b, d–f, and h) and side view (c and g) projection maps of negatively stained cruciferin complexes isolated 53 DAP and top view (i, j, l) and side view (k) projections of cruciferin isolated 60 DAP. Panels e, f, g, and j demonstrate the views of a, b, c, and i correspondingly after symmetrization. a represents a sum of 705 projections; b, 582 projections; c, 372 projections; d, 575 projections; h projections, 335 projections; i, 5000 projections; k, 5000 projections; l, 5000 projections. m shows the model of the octameric cruciferin complex based on the negatively stained projection maps. n–p demonstrate the superimposing of procruciferin density maps (purple) on projection maps from j–l correspondingly. The bar is 5 nm. The red arrows point to additional mass in every monomer in our projections, which is not visible in the monomers of the hexameric cruciferin complex solved x-ray diffraction.

tein density, which is  $1.5 \text{ g/cm}^3$  (32). Thus, each monomer, composed of an  $\alpha$  and  $\beta$  polypeptide chain, should have a molecular mass of  $\sim 50$  kDa. The obtained model is in agreement with the observations from electrophoretic analyses showing average molecular masses of  $\alpha$  and  $\beta$  chains of  $\sim 32$  kDa and 20 kDa, respectively. To interpret the projection maps, we generated the octamer of cruciferin from the x-ray structure of procruciferin and superimposed the density map of the octamer on our projection maps (Fig. 8, n–p). Importantly, by fitting the crystal structure, we gain a resolution by a factor of 5 (33). Based on the close fit, we conclude that the analyzed projections indeed represent the top and side views of the cruciferin complex in an octameric configuration. There is an additional mass in every monomer in our projections, seen as spikes (Fig. 8, e and i, red arrows), which do not belong to the monomers of the hexameric cruciferin complex solved by x-ray diffraction. This could be a result of incompleteness of the hexamer structure, which has missing residues as seen from the deposited atomic coordinates. Alternatively, crystallization conditions might cause changes in the protein configuration or subunit arrangements.

## DISCUSSION

In this study, the structural properties of cruciferin proteins as well as the supramolecular structure of the complex formed

by cruciferin subunits is investigated. In previous studies, storage protein complexes were analyzed e.g. by the expression of the proteins in a heterologous expression system, which allowed purification of the complexes to a level of purity rendering them amenable for crystallographic structural analysis. Here, we chose a different approach. Protein complexes were purified directly from freshly harvested seeds and analyzed using gel electrophoretic approaches, mass spectrometry, and single particle electron microscopy. Although the latter method is compromised in the resolution obtained at the structural level, it allows investigations of the protein from native environment. Differences in the results obtained by both approaches and their implications are discussed below.

**Suitability of the Vacuolar Fraction for Biochemical and Structural Analyses**—The purity of the isolated cruciferin fraction was demonstrated by the different gel electrophoresis procedures in combination with antibodies directed against cruciferin  $\alpha$  and  $\beta$  polypeptide chains (Figs. 3 and 4) as well as by mass spectrometry. Results from the 95 analyzed spots/bands revealed that only five proteins do not belong to the family of storage proteins. These are as follows: glyceraldehyde-3-phosphate dehydrogenase, elongation factor 1- $\alpha$ , myosinase binding protein, protein disulfide isomerase, and oleosin (supplemental Fig. 2 and supplemental Table 1). The first three proteins most likely represent cytosolic constituents, whereas the protein disulfide isomerase is reported to be an integral part of protein storage vacuoles (34). Oleosin is a component of oil bodies in *B. napus* seeds (35). The purity of the vacuolar fraction is additionally confirmed by electron microscopy. Negatively stained specimens were found to exclusively contain oligomeric Cruciferin, either in side or in top views. Therefore, the PSV fractions obtained are well suited for a detailed analysis of native *B. napus* cruciferin.

**Heterogeneity of *B. napus* Cruciferin**—The analyses of cruciferin and its polypeptide chains were carried out using different electrophoretic approaches. The results obtained by one-dimensional BN, one-dimensional SDS, two-dimensional BN/SDS, and two-dimensional IEF/SDS/PAGE, respective immunoblots, and mass spectrometry analyses suggest a strong diversity in physicochemical properties of the cruciferin polypeptide chains, proteins, and protein complexes (Table 1). In all gel systems,  $\alpha$  polypeptide chains show molecular masses between 27 and 36 and  $\beta$  polypeptide chains between 19 and 21 kDa. Partially, molecular masses differ from the calculated ones in a range of 6 kDa, especially for  $\alpha$  chains. Isoelectric points of some cruciferin polypeptides differ significantly compared with their calculated pIs in databases. In general, the  $\beta$  polypeptide chains show a very diverse pI range on IEF/SDS gels between 5.9 and 9.5. This is also reflected by the calculated pIs (6.1 and 8.6). Hence,  $\beta$  polypeptide chains can be considered to be rather basic. Surprisingly,  $\alpha$  chains, which previously were observed to have an acidic pI, are found at higher pH values (36, 37). Their apparent isoelectric points on IEF/SDS gels are all between pH 6.8 and 8.6. This clearly indicates a neutral rather than an acidic pI (Table 1 and Fig. 6).

A certain level of heterogeneity was also observed on the level of the cruciferin holo-complex. The main band for cruciferin complexes on BN gels smeared over a range of nearly 100 kDa.

<sup>a</sup> Number of amino acids, excluding the signal peptide, derived from the corresponding UniProt database entry.

<sup>b</sup> Calculated isoelectric points and calculated molecular masses, excluding the signal peptide, using the EXPASY MM/pI tool.

<sup>c</sup> Apparent isoelectric points and molecular masses upon analyses by two-dimensional IEF/SDS PAGE (Fig. 5).

This band includes protein complexes ranging from 300 to 390 kDa (Fig. 1), whereas the estimated mass of the cruciferin octamer based on EM analyses is ~420 kDa. The difference between the estimated mass of the complex and the one observed on BN gels is most likely caused by the barrel-like structure of the octamer. Indeed, the three-dimensional structure of cruciferin is considerably compact. In contrast, the structures of the respiratory complexes of *A. thaliana* mitochondria are much more irregular (complex I, for instance, has an L-like shape). Because the BN gel was calibrated by the masses of the respiratory complexes, the apparent molecular mass of the cruciferin complex is very likely to be underestimated. Apart from that, calculation of the mass from the EM projections does not take into account the presence of the central pore and space between the monomers, thereby providing slight overestimation for the mass of cruciferin.

**Phosphorylation of Cruciferin**—To explain pI variations on two-dimensional IEF/SDS gels, an immune blotting approach was carried out (Fig. 7). Western blots developed with antibodies directed against phosphoserine, phosphothreonine, and phosphotyrosine indicate stable phosphorylations on several but not all cruciferin forms separated by IEF/SDS-PAGE (Fig. 7). Similar results were previously reported for *B. napus* and *A. thaliana* (39–41). In fact, it was shown that cruciferin is one of the most phosphorylated proteins in *A. thaliana* seeds. In contrast, our MS analyses did not reveal direct evidence for cruciferin phosphorylation in *B. napus*. This negative result probably is due to the fact that phosphopeptides were not enriched during sample preparation for MS (e.g. by Immobilized metal ion affinity chromatography (IMAC) or TiO<sub>2</sub> affinity chromatography). Most likely, phosphorylation sites in cruciferins are substoichiometrically phosphorylated. As a consequence, non-phosphorylated peptides dominated the mass spectra.

**The Supramolecular Structure of Directly Isolated Cruciferin**—By combining a mild purification procedure with analyses by BN PAGE and single particle EM, we were able to structurally characterize cruciferin oligomers from mature seeds. Because proteins for crystallization experiments often are produced by overexpression in heterologous systems, mainly *E. coli*, several factors ensuring a correct assembly may be missing, e.g. signal peptide cleavage, the proteolytic cleavage of the  $\alpha$  and  $\beta$  polypeptide chains and their assembly in the endoplasmic reticulum as well as the following formation into oligomers. Furthermore, many results on seed storage proteins are obtained using defatted flours for industrial purposes or NaCl extraction, which may strongly disturb the native conformation of the pro-

teins (17, 18, 42–44). Therefore, further analyses should be carried out to verify hexameric globulin structure in seeds as reported before for other plants. Finally, globulin complexes from additional species should be characterized to obtain more general insights into their oligomeric organization.

*Acknowledgment*—We thank Dr. Holger Eubel for critically reading the manuscript.

Seed development

### ABSTRACT

The endosperm plays an important role for the development of zygotic embryos, while somatic embryos lack a seed coat and endosperm and often show physiological disorders. This study aims at elucidating the cellular and physiological processes within the endosperm of the ornamental species *Cyclamen persicum* Mill. Histological analyses were performed from 0 to 11 weeks after pollination (WAP). At 3 WAP, a syncytium was clearly visible with a globular zygotic embryo. From 4 WAP, cellularization of the endosperm, at 5 WAP a small torpedo shaped embryo, and from 7 WAP cell expansion was observed. By 11 WAP the endosperm appeared fully differentiated. Total soluble proteins were extracted from the endosperm at 4, 5, 7, 9 and 11 WAP and resolved using two dimensional isoelectric focussing/sodium dodecyl sulphate–polyacrylamide gel electrophoresis (2D IEF/SDS–PAGE). A shift from high-molecular-mass proteins to low-molecular-mass proteins during endosperm development was observed. A total of 1137 protein spots/gel were detected in the three protein fractions extracted at 7, 9 and 11 WAP. Mass spectrometry analysis of the 48 predominant protein spots in endosperm at 7, 9 and 11 WAP resulted in the identification of 62 proteins, ten of which were described for the first time in *Cyclamen*. Additionally, 186 proteins were identified using the *C. persicum* embryo proteome reference map. Proteins involved in abscisic acid signalling and oxidative stress responsive proteins were found to be important for seed development in *Cyclamen*. The new insights into endosperm physiology including storage compounds are discussed.

### 1. Introduction

Within many plant seeds, the endosperm functions mainly to provide nutrients to the embryo, thereby supporting its development and also its later germination [1–4]. In addition, the endosperm insulates the embryo from mechanical pressure imposed by the seed coat [5], and plays a role in signalling towards the embryo [4]. Recently, the function of the endosperm especially as an integrator of seed growth and development based on signalling between endosperm and embryo as well as mechanical barrier has been emphasized [6].

The endosperm, depending on the species, may be a transient tissue which is largely reabsorbed during late seed development e.g. in *Arabidopsis*, or it may be enlarged and persistent even upon

seed maturity e.g. in *Cyclamen* and cereals. In the case of *Arabidopsis*, the cotyledon offers a comparable storage function as represented by the endosperm [3,4]. Endosperm development generally progresses through several characteristic stages, i.e. syncytium formation by several nuclear divisions, cellularization, growth and differentiation and finally maturation including accumulation of storage compounds, development of desiccation tolerance and dormancy [7]. Plants are able to accumulate carbohydrates [8], proteins [9] and fatty acids [10] as storage compounds in their endosperm. Therefore the endosperm functions as the storage organ and developmental control unit for the embryo and for the germinating seed [2,11].

*Cyclamen persicum* is a popular ornamental crop with high economic relevance. For commercial propagation, the F<sub>1</sub> hybrid cultivars are of predominant meaning. However, relatively high costs for seed production due to inbreeding depression of parent lines and intensive manual work are challenging problems. Therefore, there is an interest in an alternative vegetative propagation system. Somatic embryogenesis has been reported to represent an efficient in vitro propagation technique in *Cyclamen* [12–15]. However, somatic embryos often show physiological disorders,

asynchronous development and misshaping during development. In addition, unlike zygotic embryos, somatic embryos lack a seed coat and the endosperm. One marked difference being the availability of storage compounds i.e. carbohydrates, proteins and lipids in the endosperm.

For *Cyclamen* seeds, the storage polysaccharide xyloglucan [16,17], the storage proteins 11S and 7S globulin [17] and truncated forms of enolase proposed to function as storage proteins [18] have been reported. But so far, a profound knowledge about the components and physiological processes within the endosperm development of *Cyclamen* seeds is lacking.

Proteomic studies have been shown to be a powerful tool for monitoring the present physiological status of cells and tissues under specific developmental conditions [19] and during development [20,21] and have been performed successfully for seeds and seed compartments in many crops recently, e.g. in maize [22], coffee [23] or rice [24].

In this study, we aimed (i) to identify the key events during endosperm development at the cellular level by histological analyses, and (ii) to elucidate on the basis of alterations in the protein profiles of *C. persicum* endosperm during seed development the predominant role of the endosperm for the embryo development.

## 2. Materials and methods

### 2.1. Plant material

The diploid *C. persicum* commercial F<sub>1</sub> cultivar 'Maxora Light Purple' bred by the company Varinova (Berkel en Rodenrijs, Netherlands) was grown in the greenhouse at a heating set point of 17 °C and a ventilation set point of 20 °C. Closed flower buds were emasculated and self-pollinated after 48 h. Fruits were harvested weekly from 0 (before pollination) to 11 weeks after pollination (WAP). Three biological replications were collected for each stage.

### 2.2. Histological analyses

Histological analyses were performed from day 0 (before pollination) to 11 WAP. For each stage, histological analyses were repeated twice to ensure two biological and technical replications. The samples were fixed in FAA (formaldehyde acetic acid) solution containing 67% ethanol, 20% H<sub>2</sub>O, 1.8% formaldehyde and 5% glacial acetic acid for at least 24 h and then stored at 4 °C. The tissues were dehydrated in a vacuum using graded alcohol series (70–96% ethanol and 100% isopropanol) and embedded in paraffin wax [25].

Sections of 3–8 μm were cut using a microtome and stained using FCA (Fuchsin Chrysoidine Astra blue, Morphisto, Germany) solution according to Hoenemann et al. [25] and Morphisto histology manual ([www.morphisto.de](http://www.morphisto.de)). The slides were visualized using a light microscope (Carl Zeiss, Germany) and the photographs were taken using AxioCam MR3 and edited with the AxioVision software (Carl Zeiss, Germany).

### 2.3. Proteomic analyses

#### 2.3.1. Phenolic protein extraction

Proteomic analyses were performed for tissue harvested at 4, 5, 7, 9 and 11 WAP. Three biological replicates were collected for each stage. The samples were prepared under a stereo microscope (Carl Zeiss, Germany) directly frozen in liquid nitrogen and stored at μ80 °C until the time of analysis.

Total proteins were extracted and precipitated according to Hurlman and Tanaka [26] protocol modified by Colditz et al. [27]. Whole seeds were used for proteome analyses at 4 and 5 WAP as the endosperm was still liquid (Fig. 1a and b). For 7, 9 and 11 WAP, endosperm and seed coat were collected (Fig. 1c). 60 mg (9 and

11 WAP) and 80 mg (4, 5, and 7 WAP) of endosperm tissue were pulverized in a bead mill and homogenized in extraction buffer (700 mM sucrose, 500 mM Tris, 50 mM EDTA, 100 mM KCl, 2 mM PMSF and 2% (v/v) (-mercaptoethanol, pH 8.0). Saturated phenol (pH 6.6/7.9) was added to the samples and proteins were precipitated in the phenolic phase with 100 mM ammonium acetate in methanol at –20 °C overnight.

#### 2.3.2. Two dimensional (2D) IEF/SDS-PAGE

For first dimension isoelectric focussing (IEF), immobilized dry strips (18 cm) with pH gradients 3–11 were rehydrated with protein samples in rehydration buffer (8 M urea, 2% (w/v) CHAPS, 100 mM DTT, 0.5% (v/v) IPG buffer). Isoelectric focussing was done using IPGphor system (GE Healthcare). IPG strips were equilibrated in equilibration solution I (30% (v/v) glycerol, 50 mM Tris-HCl pH 8.8, 6 M urea, 2% (w/v) SDS, a trace of bromophenol blue, 0.01 g DTT ml<sup>-1</sup> (w/v)) and equilibration solution II (same compounds like equilibration solution I, but DTT substituted by 0.025 g iodoacetamide ml<sup>-1</sup>).

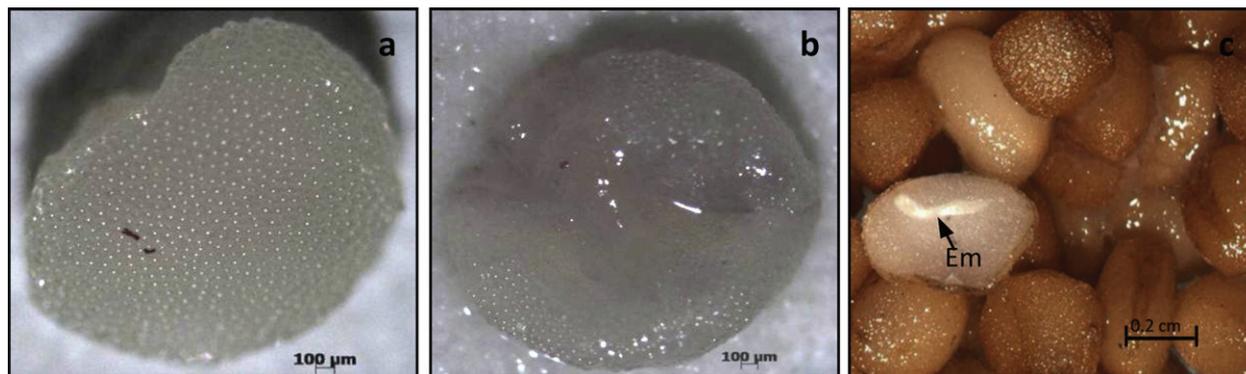

For second dimension of sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE) IPG strips were fixed horizontally onto SDS–tricine–polyacrylamide gels of 12% acrylamide. Electrophoresis was carried out for 20 h at 30 mA mm<sup>-1</sup> using Biorad Protean IIXL gel system (Biorad, München, Germany). Gels were subsequently stained overnight using colloidal Coomassie Brilliant Blue (CBB-250 G, Merck, Darmstadt, Germany) after treatment with the fixing solution (40% (v/v) methanol, 10% (v/v) acetate) for at least 2 h [28,29].

#### 2.3.3. Quantitative gel evaluation

The gels were scanned on an ImageScanner III (GE Healthcare, Freiburg, Germany) and evaluated using Delta 2D software, version 4.0 (Decodon, Greifswald, Germany) with three replicates for each group (4, 5, 7, 9 and 11 WAP). Spots detection was done automatically and occasionally corrected manually. In gel normalization was performed using the Delta 2D software for the overlays of three replicate gels each. Spots with a relative spot volume of less than 0.005% were deleted. Significant changes in spot patterns of the different endosperm groups were determined using Student's *t*-test (confidence interval ≥95%) based on the relative spot volume.

### 2.4. Mass spectrometry

Protein spots were cut out from the 2D IEF/SDS gel using a manual spot picker (Genetix; spot diameter, 1.4 mm) and were assigned the unique spot number identifier according to Delta 2D software. Mass spectrometry analyses were carried out according to [30]. The gel pieces were de-stained by washing in water, dried under vacuum and dehydrated using acetonitrile and then incubated with 0.1 M NH<sub>4</sub>HCO<sub>3</sub>. Trypsin digestion (2 mg/ml resuspension buffer [Promega] in 0.1 M NH<sub>4</sub>HCO<sub>3</sub>) was performed at 37 °C overnight. The resulting tryptic peptides were extracted by incubation with 5% formic acid in 50% acetonitrile for 15 min at 37 °C. The supernatant was set aside and a second extraction with 100% acetonitrile was performed. Finally, the supernatant was combined with the first one. Extracted peptides were dried by vacuum centrifugation and stored at μ20 °C. The peptides were analysed via LC–MS/MS using a Proxeon Easy – nLC (pre-column: 100 μm diameter/2 cm length, main column: 75 μm diameter/10 cm length; Acclaim® PepMap, Germany) and a micrOTOF – QII ESI-MS/MS (Bruker Daltonics, Bremen, Germany). Spectra were generated using the "HyStar compass post processing" software (Bruker Daltonics, Bremen, Germany). Proteins were identified using the MASCOT search algorithm against the NCBI non-redundant protein database (<http://www.ncbi.nlm.nih.gov>, RefSeq collection (Release 47, May 2011), plant sub-database),

**Fig. 1.** *C. persicum* seed: (a) at 4 WAP; (b) pierced seed at 4 WAP with liquid endosperm and (c) at 11 WAP seed showing the zygotic embryo (Em).

the SWISS-PROT (<http://www.expasy.org>) and TAIR 10 databases ([www.arabidopsis.org](http://www.arabidopsis.org)). Only proteins with a MASCOT score of at least 40 were selected. Hypothetical/unknown protein sequences were further blasted through SWISS-PROT. The identified proteins were grouped according to their physiological pathway based on KEGG PATHWAY modified by [31].

### 3. Results

#### 3.1. Histological analysis of endosperm development

Histological analyses applying FCA staining served as a basis for the proteomic analyses to identify the key events during endosperm development. At the beginning, ovules were observed before pollination had been carried out (0 WAP) in which the embryo sac was clearly visible (Fig. 2, 0 WAP). One week after pollination, the chalazal and micropylar ends of the embryo sac could be identified and the outer cell layers forming the testa were stained brown to orange indicating secondary cell wall formation and lignin/suberin accumulation. By 2 WAP, endosperm development had already begun characterized by a mass of multinucleate cytoplasm in the centre of the seed (Fig. 2, 2 WAP). At 3 WAP, the syncytium was clearly visible with a tiny globular embryo in the middle (not shown). At this stage the endosperm was at a transition stage to become cellular. Cellularization of the endosperm begun at 4 WAP from the periphery of the embryo sac. At 5 WAP, a small torpedo shaped embryo was observed within the cellularized endosperm. The development of the endosperm from 6 to 11 WAP was characterized by changes in cell shape and cell wall thickness. At 7 WAP, the endosperm was observed to consist of loosely packed cells which by 11 WAP formed a compact mass of cells. The endosperm surrounding region was observed to be a distinct development domain (Fig. 2).

#### 3.2. Comparison of zygotic embryo and endosperm proteomes

Proteomic analyses were performed in order to characterize the *C. persicum* endosperm proteome. For this purpose, 2D IEF/SDS gel electrophoresis was carried out with protein samples derived from five seed developmental stages at 4, 5, 7, 9 and 11 WAP (Fig. 3). Since the endosperm at 4 and 5 WAP was still liquid and separation from other tissue was not possible, whole seeds were analysed. After solidification of the endosperm, it was easy to isolate from the embryo as both tissues are separated by the epidermis of the embryo. Hence, proteomic analyses at 7, 9 and 11 WAP were carried out with isolated endosperm tissue. Proteomic analyses led to the resolution of approximately 1000 separate protein spots per single gel after CBB staining. From the endosperm protein gels, protein identification was achieved via two different methods:

- (i) Identification based on similar protein spot patterns when compared with the *C. persicum* digital proteome reference map for zygotic and somatic embryos [18,31] (<http://www.gelmap.de/cyclamen>). Because of a high similarity level (186 of 490 spots) in protein pattern observed between the zygotic embryo and endosperm gels (Suppl. Fig. S1), this reference map was used for protein identification in 7, 9 and 11 WAP endosperm gels. The transfer of protein spot labels from the zygotic embryo to endosperm gel was performed automatically using Delta 2D software and each spot was further verified manually. A total of 186 protein spots out of 490 detected spots were identified. Among them, 19 spots had multiple proteins identified (see Appendix A in Supporting Information).
- (ii) Additional protein identification via LC-ESI-MS/MS of selected protein spots that revealed altered abundance patterns during the time-course analysed but were not annotated in the *C. persicum* digital proteome reference map (Table 1, see also Appendix B in Supporting Information).

Mass spectrometric analyses were performed for 48 protein spots predominantly appearing in 7, 9 and 11 WAP endosperm gels. In 39 out of these 48 spots, 62 proteins were identified while 9 spots had no identity matches. This represents 81% identification rate. Ten proteins were described for the first time in *Cyclamen*, including zeaxanthin epoxidase, F-box protein, PR 10 family protein, glucose and ribitol dehydrogenase, seed maturation protein, vacuolar processing enzyme 1a, ethylene receptor, sugar carrier protein C, phytoene desaturase and wax synthase.

#### 3.3. Overall shift in proteins' molecular mass during endosperm development

The whole seed proteomes at 4 and 5 WAP had a high proportion of high-molecular-mass proteins that were partly observed also in 7 WAP endosperm gel but were characteristically lacking in the 11 WAP endosperm gel (Fig. 3a). Additionally, at early seed development stages (4 and 5 WAP), the low-molecular-mass proteins were absent (Fig. 3a). Therefore, a shift from high-molecular-mass proteins in the early seed development stages to low-molecular-mass proteins during seed maturation stage was observed (Suppl. Fig. S2).

A total of 174 protein spots were of different abundance between 7 and 11 WAP (112 spots at least 1.5-fold higher in abundance at 7 WAP, Fig. 4), an indication of the metabolic difference between these stages. In contrast, only 45 spots were of different abundance between 9 and 11 WAP (36 spots at least 1.5-fold higher in abundance at 11 WAP, Fig. 5).

**Table 1**

<sup>a</sup>Protein spot number as assigned by Delta 2D spot detection.

<sup>b</sup>Mascot score.

<sup>c</sup>Sequence coverage.

<sup>d</sup>Calculated molecular mass (kDa).

<sup>e</sup>Calculated isoelectric point.

<sup>f</sup>Molecular weight (MW) in gel as compared to the theoretically expected MW: (m) MW in gel corresponding to the theoretically expected MW  $\pm$  15 kDa; (s) MW in gel lower than theoretically expected and (l) MW in gel larger than theoretically expected.

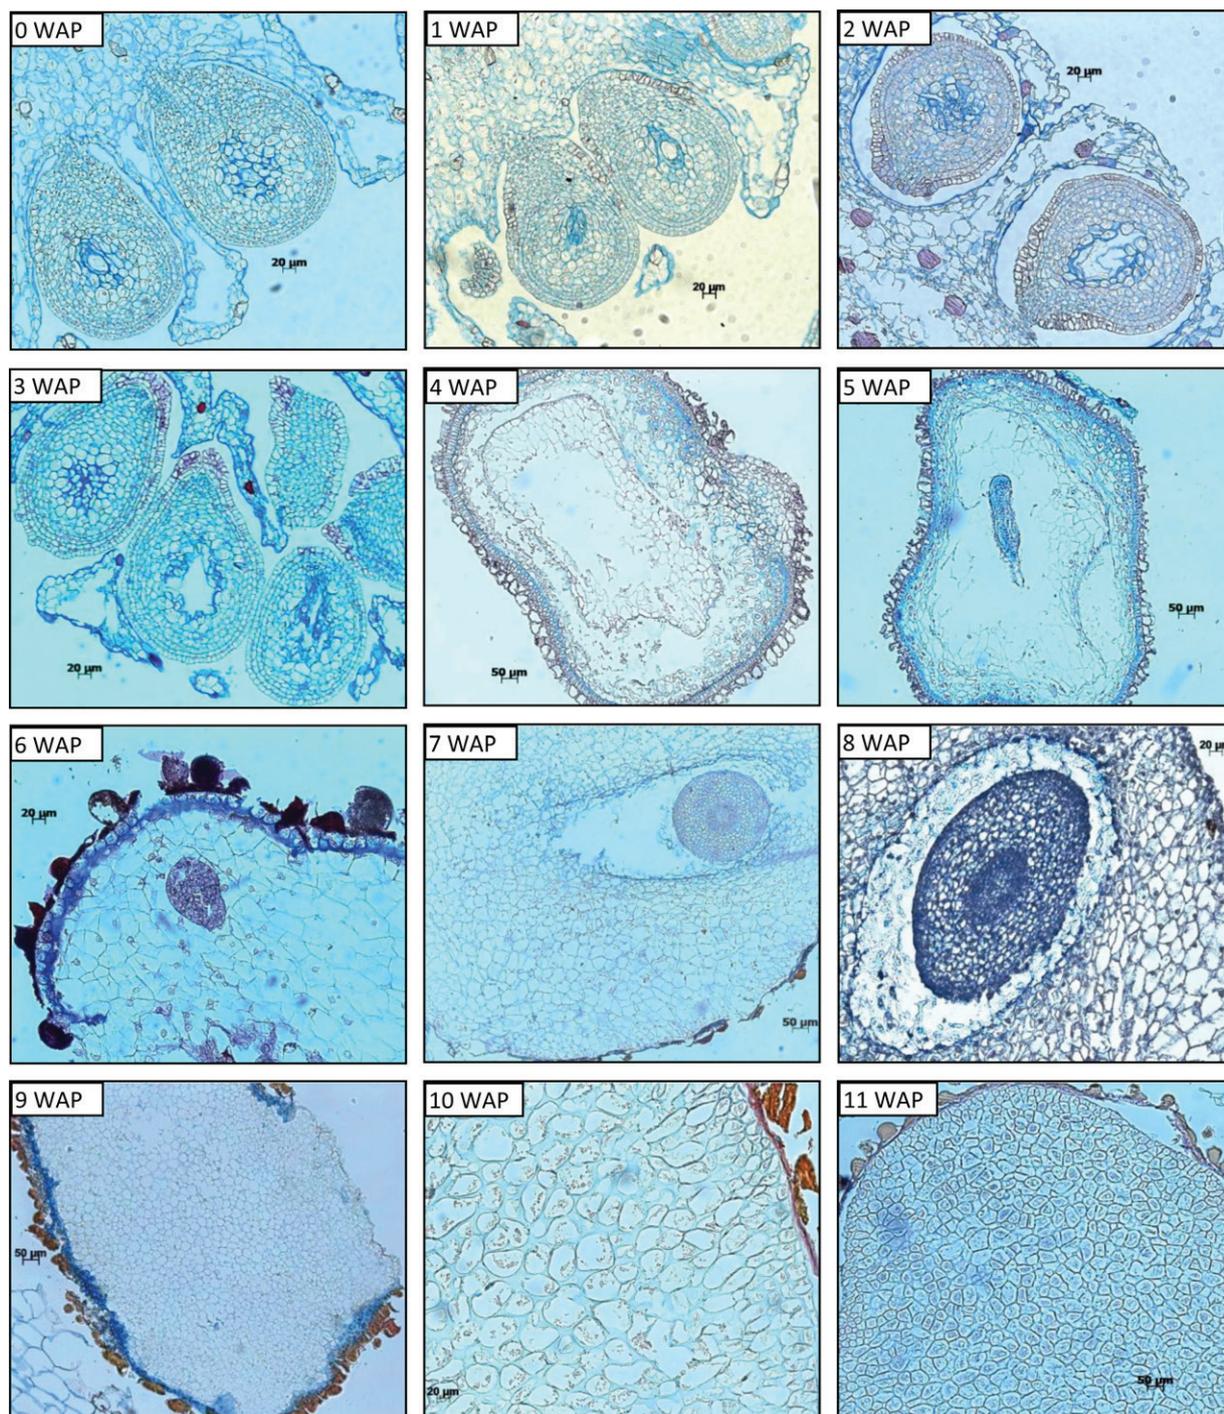

<sup>g</sup>Protein name according to the best hit of MASCOT search against NCBI nr, SwissProt and Tair 10 databases. For "hypothetical protein", "unknown" or "unnamed protein product" a BLAST search of the "unnamed" protein sequence was performed against SwissProt database.

<sup>h</sup>Physiological pathway according to KEGG PATHWAY modified by Rode et al. [31].

<sup>i</sup>Mean relative spot volume obtained in the three gel replicates of 7, 9 and 11 WAP. These values are illustrated by graphs at the right side of each row for all shown spots. The first bar (purple) represents 7 WAP, the second (red) 9 WAP and the third (green) 11 WAP.

<sup>j</sup>Coefficient of variation as calculated using Delta 2D software.

<sup>k</sup>Ratio of protein spot abundance (ratio = v (11 WAP)/v (7 WAP or 9 WAP)). Statistically significant values of at least 1.5 fold more or 1.5 fold less (all values  $\leq$  0.6) abundant protein spots are given. Green figures are indicating values of significant higher abundances in 11 WAP endosperm, purple indicates spots that are significant higher abundant in 7 WAP endosperm and red in 9 WAP endosperm.

**Fig. 2.** Histological analysis of development of *C. persicum* seed, 0–11 WAP, using Fuch sine Chrysoidine Astra blue which stains cell walls blue, lignified or cutinized cell walls in orange to brownish red and nuclei in light purple. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

### 3.4. Proteins changing in abundance during endosperm development

#### 3.4.1. Cell division and growth proteins

Several proteins involved in cell division and growth were identified, such as annexin (2 spots), cell division cycle protein (2 spots), alpha tubulin and actin 1 (4 spots) (Table 2). Annexin (spots 110 and 331) and actin 1 (spots 100 and 351) were 1.5 fold higher

abundant in 7 WAP as compared to 11 WAP indicating that there was a decrease in cell division activity from 7 WAP to 9 and 11 WAP.

#### 3.4.2. Stress related proteins

A number of proteins were identified that play a role in the control of the oxidative state of cells and in the elimination of reactive oxygen species. They are catalase, aluminium induced protein, glutathione reductase and osmotin-like protein

Table 2

<sup>a</sup>Protein spot number as assigned during Delta 2D protein spot detection. Corresponding spots of all gels are labelled with the same spot number.

<sup>b</sup>Proteins identified using *C. persicum* embryo proteome reference map [31].

<sup>c</sup>Spot ID represents the protein spot number as presented in the *C. persicum* embryo proteome reference map.

<sup>d</sup>Mean relative spot volume obtained in the three gel replicates of 7, 9 and 11 WAP. These values are illustrated by graphs at the right side of each row for all shown spots. The first bar (purple) represents 7 WAP, the second (red) 9 WAP and the third (green) 11 WAP.

<sup>e</sup>Coefficient of variation as calculated using Delta 2D software.

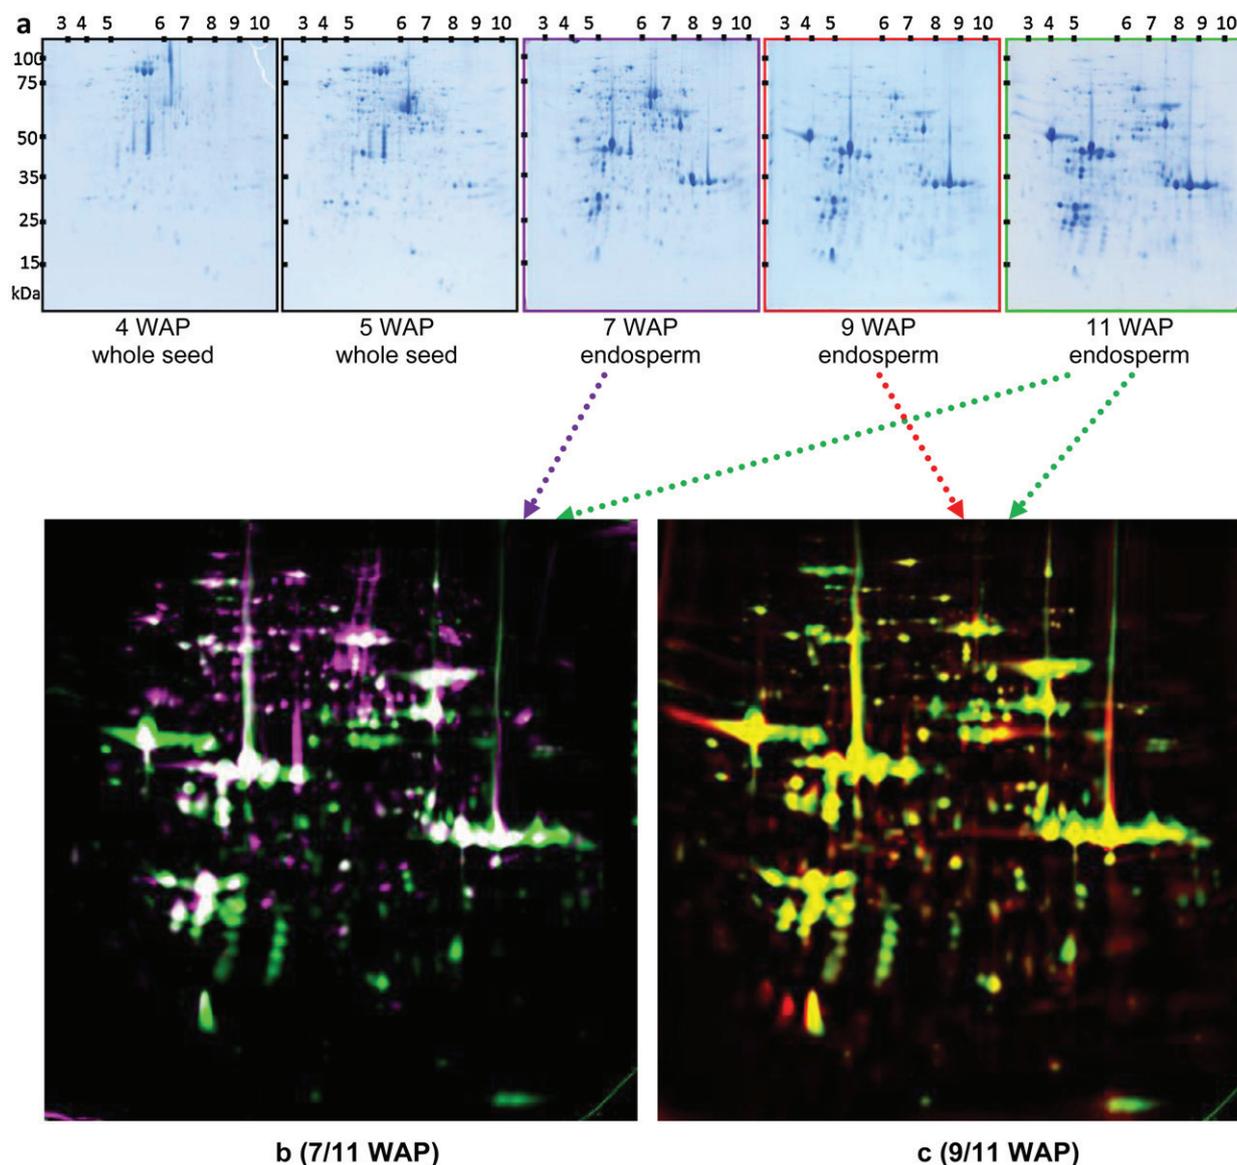

<sup>f</sup>Ratio of protein spot abundance (ratio = v (11 WAP)/v (7 WAP or 9 WAP)). Statistically significant values of at least 1.5 fold more or 1.5 fold less (all values  $\leq 0.6$ ) abundant protein spots are given. Green figures are indicating values of significant higher abundances in 11 WAP endosperm, purple indicates spots that are significant higher abundant in 7 WAP endosperm and red in 9 WAP endosperm.

and were higher abundant in 7 WAP as compared to 11 WAP, while S-formylglutathione hydrolase, universal stress protein and thioredoxin peroxidase 1 were 1.5 fold higher abundant in 11 WAP as compared to 7 WAP.

Heat shock proteins (HSP101, HSP20, HSP60 and HSP70) had predominant distribution with 28 spots indicating high protein turnover. Of these, only 15 spots were statistically significant. HSP 60 (spots 43 and 46) was 1.5 fold higher abundant in 7 WAP as compared to 11 WAP. HSP 20 and HSP 70 did not show any clear pattern of expression.

### 3.4.3. ABA pathway

Several proteins involved in ABA biosynthesis signalling pathway were found to be differentially abundant: zeaxanthin epoxidase, ZEP (spots 15, 349, and 416), phytoene desaturase (spot 346) and SAL1 phosphatase. ZEP was identified in three spots with different molecular weight and isoelectric point, of which, 2 spots were found increased from 7 to 11 WAP and one was reduced 7 to 11 WAP. Phytoene desaturase was 1.5 fold higher abundant in 11 WAP as compared to 7 WAP.

**Fig. 3.** (a) IEF/SDS gels of the five seed development stages selected for proteomic analyses. (b) IEF/SDS overlay image of 7 and 11 WAP endosperm proteomes (each three replicates) using Delta 2D software. Green spots were at least 1.5-fold more abundant at 11 WAP and purple spots were at least 1.5-fold more abundant at 7 WAP. Spots with similar abundance in both endosperm stages appear in white. (c) IEF/SDS overlay image of 9 and 11 WAP endosperm proteomes (each three replicates) using Delta 2D software. Green spots (36) were at least 1.5-fold more abundant at 11 WAP and red spots (9) were at least 1.5-fold more abundant at 9 WAP. Spots with similar abundance in both endosperm stages appear in yellow. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

Further evidence for plant hormone signalling being involved in endosperm and probably embryo development came from the identification of BR signalling kinase (spot 313) (brassinolide signalling) and ethylene receptor 1 (spot 312) (both higher abundant in endosperm 11WAP, Fig. 5).

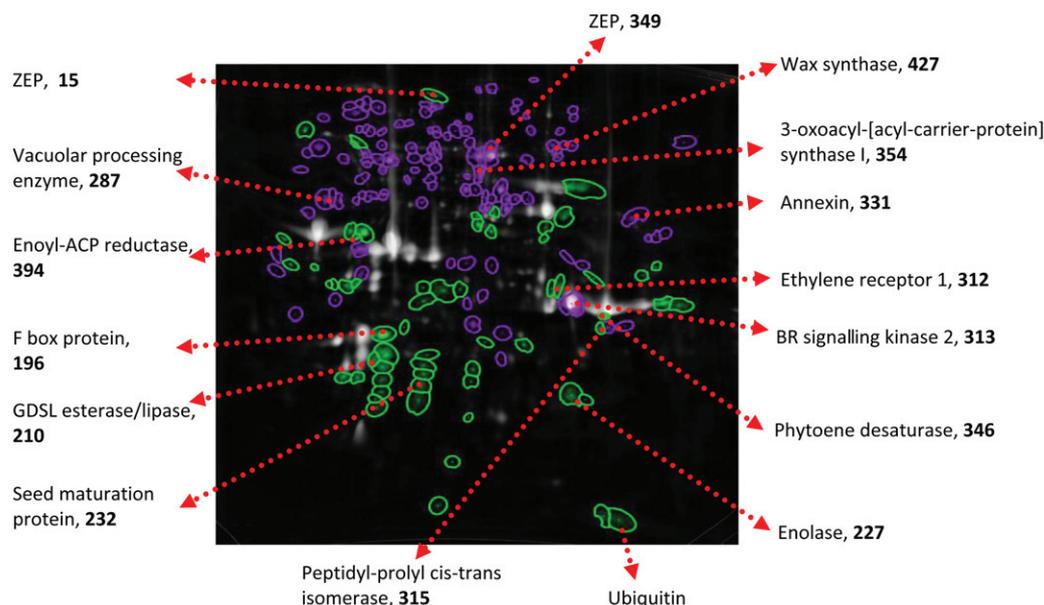

#### 3.4.4. Storage reserves in *Cyclamen* seed

One protein spot was identified as 7S globulin (spot 416) which had been previously described in *Cyclamen* endosperm [17], but no further classical storage proteins were identified in the mass spectrometric analyses. The enzyme xyloglucan endotransglycosylase (XTH) which is involved in the production of xyloglucans, the special storage carbohydrates of *Cyclamen*, was also identified at the same spot as previously described by Winkelmann et al. [17]. This spot increased in volume from 7 to 11 WAP.

Several proteins were identified that play a role in the fatty acid/lipid pathway. They are 3-oxoacyl-[acyl-carrier-protein]

synthase I, Enoyl-ACP reductase, GDSL esterase/lipase, and wax synthase. These results suggest that lipids are storage reserve in *Cyclamen*. Wax synthase (spot 427) and 3-oxoacyl-[acyl-carrier-protein] synthase I (spot 354) were 1.5 fold higher abundant at 7 WAP while Enoyl-ACP reductase (spot 394) was 1.5 fold higher abundant at 11 WAP.

A large proportion of the proteins identified belong to the enolase group (27 spots). These include both enolase 1 and 2 as described in Rode et al. [18]. In the comparison of 11 and 7 WAP groups, 6 enolase spots were significantly higher abundant (at least 1.5-fold) in 7 WAP while 9 enolase spots were significantly higher abundant in 11 WAP. The enolase spots that were higher abundant in 11 WAP correspond to the 'small enolases' which were first described for *Cyclamen* by Rode et al. [18]. Truncated forms of enolase lacking the catalytic groups, found in high abundance in *C. persicum* zygotic embryos, have been proposed to be candidates for a new group of storage proteins so far not described in plants [18].

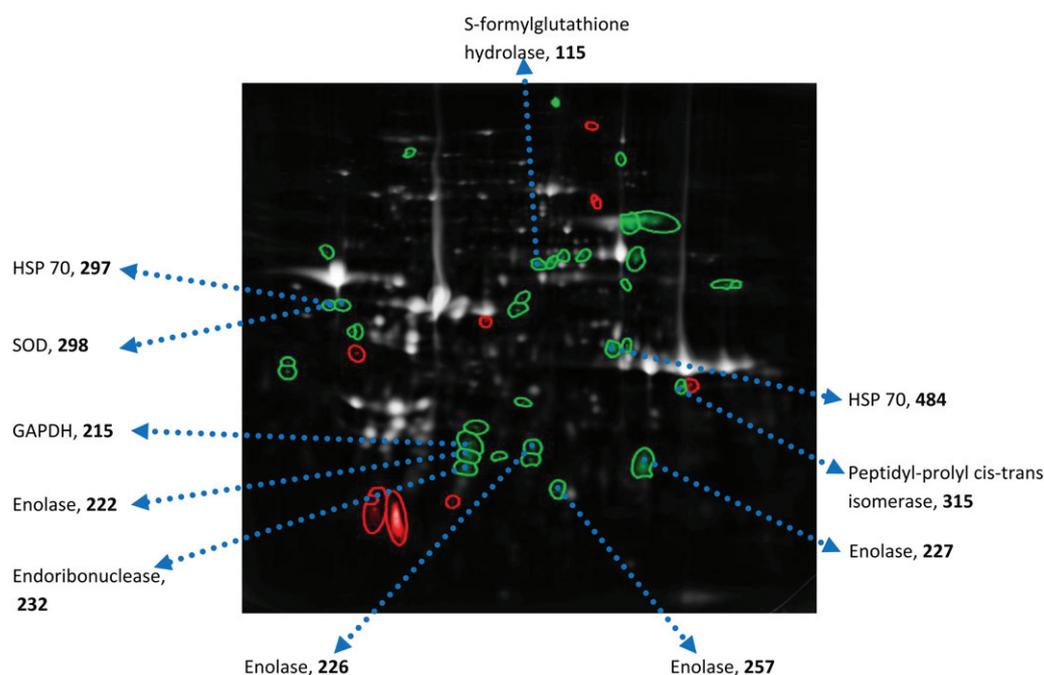

**Fig. 4.** Proteins of significantly changed abundance between the 7 and 11 WAP endosperm proteomes. Green spots were at least 1.5-fold more abundant at 11 WAP and purple spots were at least 1.5-fold more abundant at 7 WAP. Spots with similar abundance in both endosperm stages appear in white. Proteins discussed in the text are indicated. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

## 4. Discussion

### 4.1. Key events in endosperm development in *C. persicum*

After several nuclear divisions, the syncytium stage of endosperm development was clearly visible at 3 WAP, while cellularization of the endosperm was observed from 4 WAP (Fig. 2). This correlates with Hoenemann et al. [25] who also reported cellularization of *Cyclamen* seed at 30 days after pollination. Endosperm cellularization was observed to begin from the periphery of the seed, by formation of cell walls in the multinucleate cytoplasm,

characterized by addition of new layers of cells until closure in the centre. This indicates that *Cyclamen* also undergoes nuclear type of endosperm development as observed in many cereals and legumes [4,32,33]. In *Arabidopsis*, cellularization was reported to begin from the micropylar domain when the embryo reaches the globular stage of development [34]. This could also be true for *Cyclamen* as the globular embryo was first observed at 3 WAP while cellularization of the endosperm was seen to begin from 4 WAP. Endosperm cellularization appeared to be complete between 7 and 8 WAP. After cellularization, the endosperm was observed to increase in size through cell division and cell elongation as was previously reported

**Fig. 5.** Proteins of significantly changed abundance between the 9 and 11 WAP endosperm proteomes. Green spots (36) were at least 1.5-fold more abundant at 11 WAP and red spots (9) were at least 1.5-fold more abundant at 9 WAP. Spots with similar abundance in both endosperm stages appear in white. Proteins discussed in the text are indicated. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

in a flow cytometric study by Schmidt et al. [35] and by 11 WAP, the endosperm appeared to be fully differentiated consisting of a compact mass of cells.

Small globular zygotic embryos were observed at 3 WAP within the multinucleate endosperm. In a histological analysis of *C. persicum* zygotic embryos, globular embryos were first observed at 30 days after pollination [25]. At 5 WAP, a tiny torpedo-shaped embryo was detected and from 9 to 11 WAP, mature torpedo-shaped embryos were observed.

The endosperm cell wall was observed to be thick, characterized by the deep blue colour of the FCA stain (Fig. 2). In *C. purpurascens*, using electron microscopy, the endosperm cell wall was reported to be 'pitted' with unevenly thickened cell walls and dark hollows on the inside cell wall surface [36]. Endosperm cell walls contain little cellulose and large amounts of hemicelluloses, e.g. xyloglucan, which has also been reported to be a storage polysaccharide in *Cyclamen* [16,17]. These specialized cell walls are an important source of carbohydrates during germination, and they function in water retention, signalling, mechanical protection of the embryo and dormancy [34].

#### 4.2. High similarity of zygotic embryo and endosperm proteomes

There was high similarity level (186 of 490 spots) in protein pattern observed between the zygotic embryo and endosperm proteome (Suppl. Fig. S1). These included the 7S and 11S globulin, the small enolases and XTH enzyme among others. The same similarity between the endosperm and zygotic embryo has also been reported for tomato [37] and *Jatropha curcas* [38]. These indicate the great similarity in regard to function and metabolism between the zygotic embryo and endosperm. Additionally, the existing differences still indicate the novel role played by each of these tissues. However, it has to be stressed, that the applied gel-based proteomic approach considered only proteins of relatively high abundance.

#### 4.3. Decreasing cell division and primary metabolism is in line with previous reports of seed development in *Cyclamen*

A decrease in abundance of cell division related proteins was observed between 7 and 9/11 WAP pointing to a decrease in cell division activity. Gallardo et al. [39] reported a decreased abundance of annexin before accumulation of major storage proteins in *M. truncatula*. Schmidt et al. [35] using flow cytometry likewise showed the mitotic activity of *C. persicum* endosperm to be high at 28 days after pollination, decreasing sharply up to 49 days and remaining relatively low up to 119 days after pollination. The decline in mitotic activity is an indication that cell growth occurring at these stages is a result of cell elongation and expansion, characteristic of seed filling stage.

Six enzymes were identified that are involved in TCA cycle, including 2-oxoacid dehydrogenase family protein, aconitase, isocitrate dehydrogenase, dihydrolipoamide s-acetyltransferase, malic enzyme and succinate dehydrogenase. These proteins were decreasing in abundance from 7 to 11 WAP. Mechin et al. [22] also reported a similar trend for TCA cycle enzymes in maize endosperm, between 4 and 21 days after pollination. Furthermore, pyruvate dehydrogenase which catalyses conversion of pyruvate to acetyl-CoA, linking glycolytic pathway to TCA cycle [40], was also decreasing in abundance from 7 to 11 WAP. This is an indication that in later stages of seed development, a proportion of the pyruvate synthesized by glycolysis does not join the TCA cycle. It is important to note that pyruvate can be converted back to carbohydrates through gluconeogenesis, to fatty acids through acetyl-CoA or used in amino acid metabolism. This decrease in TCA cycle enzymes in later stages of seed development could suggest that pyruvate

synthesized at later stages of seed development is used for accumulation of seed storage reserves.

#### 4.4. Storage proteins in *Cyclamen*

The endosperm is a storage tissue, characterized by the accumulation of storage compounds in high amounts. Indeed, in this study we could identify 7S globulin and the putative storage protein group of small enolases to be especially high abundant in the latest stages of endosperm development (11 weeks > 9 weeks > 7 weeks). This is in accordance to Winkelmann et al. [17] and Rode et al. [18,41] who had shown these proteins in endosperm and matured embryos of *Cyclamen*, respectively. Reinhardt [42] illustrated that *Cyclamen* seeds accumulate all three categories of energy rich molecules, such as starch, fatty acids and proteins in comparable ratios. Concerning this fact, there should be more storage proteins in the endosperm regarding quality and quantity than those two protein species identified in the recent study. The lack of storage protein identification could be due to technical reasons. The proteins could not be purified from the tissue or resolved by the gel e.g. due to their hydrophobic character (e.g. the major seed storage proteins in grasses, prolamines are soluble in 60–70% ethanol [9]) or size (proteins with a higher molecular weight than 150 kDa and lower than 5 kDa cannot be resolved by the gel system used here). In addition, the lack of sequence information for the non model organism *Cyclamen* is a bottleneck for the identification of species specific storage proteins. An enrichment of low molecular proteins in the later stages of endosperm development could be an indicator of "small" units of so far unknown storage protein complexes.

#### 4.5. Other storage compounds in *Cyclamen*

Besides the above discussed storage proteins that accumulate in protein bodies [42], *Cyclamen* seeds contain carbohydrates and fatty acids/lipids as further storage reserves as demonstrated in thin sections by staining [42]. Regarding carbohydrates, xyloglucans, the special storage carbohydrates found in secondary cell walls of *Cyclamen* [16] were most likely assembled in endosperm cells in the later phase of seed development by the enzyme xyloglucan endo-transglycosylase (XTH). Since XTHs had been identified before in endosperm tissue of another genotype [17], this finding proves the reproducibility and stability of the proteomic data. Xyloglucans are hemicelluloses being present in the primary cell wall of somatic cells, but also serving as densely packed and easy to mobilize carbohydrate stores in endosperm cell walls, e.g. in *Myrsinaceae* to which also the genus *Cyclamen* belongs [34].

Other evidence for the important role of carbohydrates as storage reserves can be deduced from the high percentage (34%) of identified endosperm proteins that are involved in carbohydrate metabolism. Sugars not only serve as carbon and energy sources, but also as signalling molecules, osmotic regulators [43] and membrane protectants during desiccation stress [44]. Sugars are considered to be supplied by the endosperm to the growing embryo. This requires sugar transporters one type of which – sugar carrier C – was identified in the course of the present study. Sugar transporters are membrane-bound and highly hydrophobic and generally not separable by 2D IEF/SDS PAGE. However, the phenolic protein extraction used for *Cyclamen* endosperm tissue led to their detection in four different spots (313, 314, 326, and 346). The exact localization and direction of transport needs further investigations.

*Cyclamen* endosperm serves as storage organ containing proteins or amino acids and carbohydrates providing energy, carbon, nitrogen and further components to the embryo during later germination. Moreover, fatty acids/lipids are storage reserves in *Cyclamen* seed as demonstrated by Reinhardt [42] by the detection of lipid

bodies using sudan black staining and supported in this study by identification of enzymes involved in fatty acid/lipid metabolism.

#### 4.6. Stress and ABA signalling are important for seed development

Several enzymes involved in stress regulation processes were found to be induced during the analysed time course of endosperm development. This list of proteins includes proteins which generally function in cellular stress response (e.g. universal stress proteins; spots 68, 70, 140, and 181) as well as the predominant abundant heat shock proteins of different classes, which are involved in protein folding and processing mechanisms (molecular chaperones) as well as stress-related protein structural alterations. In addition, they contribute to processes that have been associated with seed longevity, such as thermotolerance, tolerance to embryo desiccation or oxidative stress resistance [45]. Next to several HSP members, enzymes involved in detoxification of reactive oxygen species (ROS) showed also predominant values of abundance, such as catalases (spots 59, 61, 426, and 428), peroxiredoxin type II (spot 179), thioredoxin peroxidase 1 (spot 176), manganese/copper/zinc and iron superoxide dismutases (spots 312; 194, 213, 298, and 422), glutathione reductase (spot 350), S-formylglutathione hydrolase (spot 115), apoptosis-related protein (spot 203), aluminium induced protein (spot 127), anti-oxidant 1 (spot 262) and osmotin-like proteins (spots 306 and 478). Thus, these oxidative stress responsive proteins play a major role during endosperm development in *C. persicum*. For the induced catalases and peroxiredoxins, antioxidant-responsive elements (ARE) core sequences were identified in the corresponding promoter regions of the *Arabidopsis* and maize genes and putative protein-DNA interactions may allow fast responses to altered ROS levels [46,47]. Future studies will aim at gaining insights into the role of ROS during embryogenesis and endosperm development in *C. persicum*.

In addition, the *Arabidopsis AtPER1* and its homologue from barley, *Per1*, have been described to be dormancy-related and thus highly involved in seed physiology during desiccation and also resumption of respiration upon rehydration of germinating seeds, providing protection against ROS [48,49]. On the other hand, more recent results indicate that these peroxiredoxins function as molecular chaperones under oxidative stress conditions via inhibition of germination rather than regulators of seed dormancy [50,51]. However, these proteins are specific for seed physiology since they are localized to embryo, endosperm and aleurone cells [51].

Although the induction patterns of the protein members of the anti-oxidative system are quite diverse during the analysed stages of *C. persicum* endosperm development, by trend most enzymes are higher abundant at 11 WAP than at the previous 9 and 7 WAP stages. This is true for the superoxide dismutases, glutathione reductase, peroxiredoxin, thioredoxins and anti-oxidant 1. In contrast, catalases and apoptosis-related protein are higher abundant at 7 WAP. Interestingly, the enzymes related to ABA biosynthesis show a similar diversity of abundance patterns. In general, endogenous ABA acts as a positive regulator for the late maturation program in embryogenesis while at the same time is a negative regulator of the germination programs [52]. The expression of peroxiredoxins in endosperm and embryo from the cotyledon stage of development are found to be ABA-dependent via ABA-responsive elements (ABRE), following their induction via ARE promoter elements at earlier stages [53].

In conclusion, this study has identified the time course of the major cellular events during endosperm development in *C. persicum*. Proteomic analyses supported the histological as well as previous flow cytometric studies and revealed several insights into major metabolic changes and storage reserve synthesis. Accomplished by metabolomic analyses the in vitro system of somatic embryogenesis may be optimized by adjusting culture medium

and culture conditions in a way that mimics the situation in the endosperm. Therefore, the application of abscisic acid for maturation of somatic embryos should be tested and optimized in terms of concentration and time course. Secondly the role of reactive oxygen species during development of somatic embryos will be investigated in future studies.

### ABSTRACT

Somatic embryogenesis can efficiently foster the propagation of *Theobroma cacao*, but the poor quality of resulted plantlet hinders the use of this technique in the commercial scale. The current study has been initiated to systematically compare the physiological mechanisms underlying somatic and zygotic embryogenesis in *T. cacao* on the proteome level. About 1000 protein spots per fraction could be separated by two-dimensional isoelectric focusing/SDS PAGE. More than 50 of the protein spots clearly differed in abundance between zygotic and somatic embryos: 33 proteins spots were at least 3-fold higher in abundance in zygotic embryos and 20 in somatic embryos. Analyses of these protein spots differing in volume by mass spectrometry resulted in the identification of 68 distinct proteins. Many of the identified proteins are involved in genetic information processing (21 proteins), carbohydrate metabolism (11 proteins) and stress response (7 proteins). Somatic embryos especially displayed many stress related proteins, few enzymes involved in storage compound synthesis and an exceptional high abundance of endopeptidase inhibitors. Phosphoenolpyruvate carboxylase, which was accumulated more than 3-fold higher in zygotic embryos, represents a prominent enzyme in the storage compound metabolism in cacao seeds. Implications on the improvement of somatic embryogenesis in cacao are discussed.

## 1. Introduction

Cacao (*Theobroma cacao* L) is a tropical tree of the Malvaceae family [1] that has a high economic value because it is the main source of chocolate. Furthermore, there is a growing interest in cacao due to its high content of polyphenols which

have been suggested to prevent brain and cardiovascular diseases [2–5]. Despite its utility, the propagation of cacao is still limited because of its allogamous mating system [6] that results in inbreeding depression of parental lines. For this reason, somatic embryogenesis has been developed as an alternative strategy for the large scale propagation of elite

genotypes of cacao. Studies carried out to date on somatic embryogenesis in *T. cacao* were focused at the morphological, biochemical and gene expression level. It was the aim of most of these studies to define a medium for optimal induction of embryos [7–12]. Despite all these efforts, plantlets resulting from somatic embryos still exhibit a disturbed development and poor conversion ability. Insufficient accumulation of storage compounds and enzymatic imbalances in somatic embryos were earlier suspected to cause developmental irregularities in cacao [13] and in carrot [14].

The early seedling growth of angiosperms depends both on the storage compounds accumulated during maturation of the embryo and also on the enzymatic system that mobilizes nutrient elements to provide optimal germination. Protein mobilization releases reduced nitrogen needed for growth and development [15]. Sugar compounds such as starch and sucrose act as energy suppliers with lipid reserves [16]. In *Arabidopsis*, the use of metabolic inhibitors revealed that transcription is not required for the completion of germination; the potential of germination consequently is considered to be programmed during embryo and seed maturation [17]. Therefore, maturation is a critical point to evaluate the potential quality and viability of somatic embryogenesis-derived seedlings. In order to establish somatic embryogenesis in cacao as a standard technique in commercial scale, it is of prime interest to investigate the physiological processes that govern maturation with the hope to enhance conversion ability of somatic embryos.

Proteomics is a set of biochemical tools which are used to describe the expression, function, and regulation of the entire set of proteins encoded by an organism. Proteins are molecules that directly influence cellular biochemistry; thus, the proteome is thought to reflect more accurately the cellular state than the transcriptome which only represents an information intermediate during the process of protein biosynthesis [18–20]. The continuing development of MS-based proteomics led to gradually improved capacities of protein separation, identification and quantification. From the pioneer 2-D gel electrophoresis procedures to the most accurate linear quadrupole ion trap-orbitrap system, impressive strides have been achieved in terms of resolution, mass accuracy and throughput [21]. Hence, proteomics, which first was applied to plant biology about two decades ago, has yielded valuable information for the comprehensive understanding of a broad range of physiological processes [20,22–24].

The efficiency of proteomics to analyze physiological processes makes it a promising approach to investigate somatic embryogenesis. This is reflected by the increasing number of proteome studies in the field of somatic embryogenesis. Several plant systems such as *Picea glauca* [25], *Cyclamen persicum* [26–29] and *Phoenix dactylifera* [30] have been investigated. In cacao, proteome studies are still at an early stage [31]. The few studies in cacao based on this technology mostly focused on improving cacao derived products through post-harvest treatments [32–34]. In the present study, two dimensional gel electrophoresis coupled to protein identification by mass spectrometry is used to compare the proteomes of *T. cacao* somatic embryos with their zygotic counterparts at the torpedo stage. New insights into embryogenesis and germination physiology in *T. cacao* are presented which are relevant for

the further improvement of this prominent regeneration strategy (somatic embryogenesis).

## 2. Materials and methods

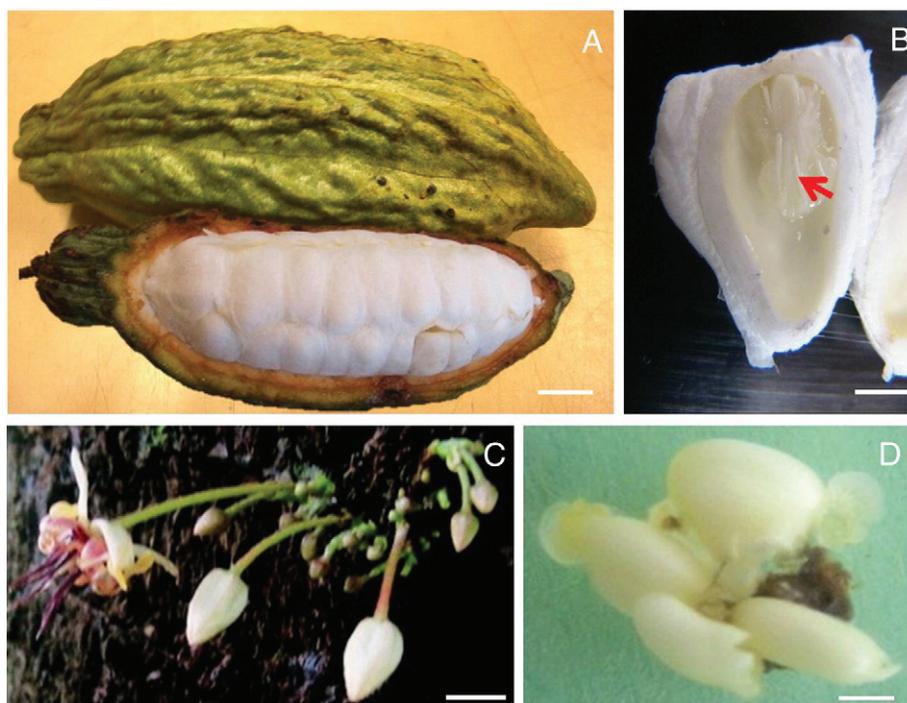

### 2.1. Plant material

In the frame of our investigation, zygotic and somatic embryos were investigated by a comparative proteomic analysis. Both types of embryos were investigated at the torpedo stage, a stage comparable to stage IIIz defined by Alemanno et al. 1997 [13]. Studies were carried out on the cacao genotype “PA 150” (PA stands for Parinari, a local name in Peru), which is included in the gene-bank of the Institute of Agricultural Research for Development at Nkolbisson (Yaounde, Cameroon). This genotype is known for its high productivity and its resistance to *Phytophthora* [35].

Zygotic embryos were harvested at the torpedo stage from 12-week-old fruits (Fig. 1A). At this stage the endosperm surrounding the zygotic embryos was liquid (Fig. 1B). The protocol used to produce somatic embryos is taken from Minyaka et al. 2008 [11]. Driver and Kuniyuki [36] mineral solution (known as DKW solution) was used to prepare all culture media. The somatic embryogenesis process is divided into three steps. The first step lasted 14 days: petals and staminodes (starting material) of immature floral buds (Fig. 1C) were cultured in PCG (primary callus growth) medium. This medium was supplemented with 250 mg l<sup>-1</sup> glutamine, 100 mg l<sup>-1</sup> myo-inositol, 1 ml l<sup>-1</sup> DKW vitamin stock (100 mg ml<sup>-1</sup> myo-inositol, 2 mg ml<sup>-1</sup> thiamine-HCl, 1 mg ml<sup>-1</sup> nicotinic acid and 2 mg ml<sup>-1</sup> glycine), 20 g l<sup>-1</sup> glucose, 18 μM 2,4 dichlorophenoxyacetic acid (2,4-D) and 45.4 nM TDZ (Thidiazuron). As a second step, developing callus cultures were transferred to SCG (secondary callus growth) medium for 14 days. This SCG medium was supplemented with 0.5 ml l<sup>-1</sup> DKW vitamin, 20 g l<sup>-1</sup> glucose, 9 μM 2,4-D and 1.2 μM kinetin. At the third step, calluses were maintained for 21 days in ED (embryo development) medium which is a growth regulator free medium supplemented with 1 ml l<sup>-1</sup> DKW vitamins, 30 g l<sup>-1</sup> sucrose and 1 g l<sup>-1</sup> glucose. Some torpedo embryos were visible after this first cultivation on ED medium, but two additional rounds of subcultures of three weeks each were required to increase the number of embryos.

### 2.2. Protein extraction

Three independent extractions (biological replicates) for each embryo type were carried out. The entire embryo was used as starting material for total protein extractions using a phenol based procedure [37]: 100 mg of harvested plant material was shock frozen in liquid nitrogen, then pulverized in a bead mill and subsequently dissolved in extraction buffer (700 mM sucrose, 500 mM Tris, 50 mM EDTA, 100 mM KCl, 2% (v/v) β-mercaptoethanol and 2 mM PMSF, pH adjusted to 8.0). The dissolved plant material was incubated on ice for 30 min and saturated phenol (pH 6.6/7.9; Amresco, Solon, USA) was added. After incubation, several centrifugation steps were carried out according to Colditz et al. [37]. Finally, proteins

**Fig. 1** – Zygotic and somatic embryos of *T. cacao*, genotype PA 150. (A) 12-week-old fruit, a closed fruit beside an opened (bar=1.5 cm). (B) Longitudinal section of one seed displaying a zygotic embryo (labeled with a red arrow) embedded in liquid endosperm (bar=0.25 cm). (C) Immature floral buds used as starting material for somatic embryogenesis (bar=0.5 cm). (D) Somatic embryos after 6 weeks of differentiation on solid medium free of growth regulator (bar=0.5 cm).

were precipitated with 100 mM ammonium acetate in methanol at  $-20^{\circ}\text{C}$  overnight. The resulting protein pellet was washed thrice at  $4^{\circ}\text{C}$  with 100 mM ammonium acetate in methanol and finally once with 80% acetone.

### 2.3. Two-dimensional IEF/SDS-PAGE and protein staining

Three independent electrophoresis runs were performed from each type of material. Proteins were separated in the first gel dimension according to their isoelectric point. The soluble protein fraction extracted from 100 mg fresh embryo tissue was resuspended in 350  $\mu\text{l}$  rehydration buffer encompassing 8 M urea, 2 M thiourea, 2% (w/v) CHAPS, 100 mM DTT, 0.5% (v/v) IPG-buffer (pH 3–11, GE Healthcare, Freiburg, Germany) and a trace of bromophenol blue. The dissolved proteins were then loaded on Immobiline dry strip gels (18 cm, pH 3–11 non-linear, GE healthcare, Freiburg, Germany), overlaid with mineral oil and electrofocused for 24 h with voltages set from 30 to 8000 V according to Mihr and Braun [38] using an IPGphor apparatus (GE Healthcare, Munich, Germany). Following IEF, the IPG strips were immediately treated with equilibration buffer (50 mM Tris-HCl, pH 8.8, 6 M urea, 30% [v/v] glycerin and 2% [w/v] SDS) containing 1% DTT for 15 min, followed by another treatment for 15 min with equilibration buffer containing 2.5% iodoacetamide. The second electrophoretic dimension was performed on 12% polyacrylamide Tricine-SDS gels [39,40]. Gels were run at 30 mA for 20 h using the Biorad Protean II-XL gel apparatus (Biorad, Munich, Germany). After gel electrophoresis runs, the gels were fixed with 10% (v/v) acetate in 40% (v/v) methanol for at

least 2 h and stained with Coomassie Blue CBB G-250 (Merck, Darmstadt, Germany) [41,42].

### 2.4. Quantitative analysis of zygotic and somatic embryo proteomes

Three gels from each type of the studied material were considered for the quantitative analysis. Evaluation of 2D gels was carried out according to Berth et al. [43]. Briefly, scans of Coomassie stained gels were analyzed with DELTA 2D software, version 4.0 (Decodon, Greifswald, Germany). Spots were detected automatically and some minor corrections were performed manually. A student's t-test ( $p\text{-value} \geq 0.05$ ) based on the normalized relative spot volume was applied to determine significant alteration in spot pattern between zygotic and somatic embryo proteomes. Spots of at least 3 fold alteration in abundance with a  $p\text{-value} \geq 0.05$  were considered to represent significant differences in protein levels and analyzed in more detail.

### 2.5. Mass spectrometry analysis and physiological clustering of identified proteins

Spots of interest were picked manually from the Coomassie stained gels using a GelPal Protein Excision System (Genetix, Queensway, U.K.) and in-gel proteolytic digestion with trypsin was carried out as previously described by Klodmann et al. [44]. In brief, acetonitrile was used for dehydration of gel pieces which were then processed for cysteine alkylation through two

successive incubations of 30 min, first at 56 °C in 20 mM DTT and secondly at room temperature in 55 mM iodoacetamide. The proteolytic digestion was based on incubation of the dehydrated gel pieces overnight at 37 °C in trypsin solution (2 µg trypsin [Promega, Madison, WI, USA] per ml resuspension buffer [0.1 M NH<sub>4</sub>HCO<sub>3</sub>]). Afterwards, tryptic peptides were extracted with acetonitrile at 37 °C; basic peptides were extracted with 5% formic acid at the same temperature.

Mass spectrometric analysis of resulting tryptic peptides was performed with the EASY-nLC System (Proxeon) coupled to a MicroTOF-Q II mass spectrometer (Bruker, Daltonics). Proteins were identified using the MASCOT search algorithm ([www.matrixscience.com](http://www.matrixscience.com)) against UniProtKB ([www.expasy.org](http://www.expasy.org)) and NCBIInr ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)) databases. Only proteins with a ppm below 20, a MASCOT score above 50 and coverage by at least 2 unique peptides were considered and functionally classified according to the KEGG PATHWAY Database (<http://www.genome.jp/kegg/pathway.html>). Categories were adjusted for seed metabolism by adding functional groups e.g. “stress response” and “defense”.

### 3. Results

Somatic embryo production in *T. cacao* is nowadays well mastered as demonstrated by the studies of Li et al. 1998 [7], Minyaka et al. 2008 [11] and Niemenak et al. 2008 [12]. The most challenging issue at the moment is the conversion of these embryos into healthy plantlets. Any improvement in this respect would represent an important step towards usage of somatic embryogenesis in *T. cacao* on a commercial scale. The present study aims at elucidating the physiological mechanisms that govern embryogenesis of this economically important plant species. This issue is addressed by a comparative proteomic-based investigation of zygotic and somatic embryos. Both types of embryos were cultivated up to an equivalent developmental stage: the torpedo stage (Fig. 1B, D). Somatic embryos showed an asynchronous development and were frequently misshaped, while their zygotic counterparts appeared morphologically well-shaped and homogeneous. Only well-shaped somatic embryos were processed for proteomic analyses.

#### 3.1. Two-dimensional analysis of proteomes from zygotic and somatic embryos

Total protein fractions extracted from somatic and zygotic embryos were separated by 2D IEF/SDS-PAGE. Visual inspection of the gels revealed that both fractions were composed of similar components (spots on the 2D gels). However, individual protein abundances largely differed between the two fractions. Overall, about 1000 spots were detectable per gel in somatic and zygotic embryos (Fig. 2A). To accurately evaluate quantitative changes in protein abundance between the two types of embryos, protein gels were analyzed by the DELTA-2D software package. Firstly, three biological repetitions for each type of embryo were used to calculate average gels. Secondly, the average gels for somatic and zygotic embryos were compared. This comparison revealed that 33 protein spots were at

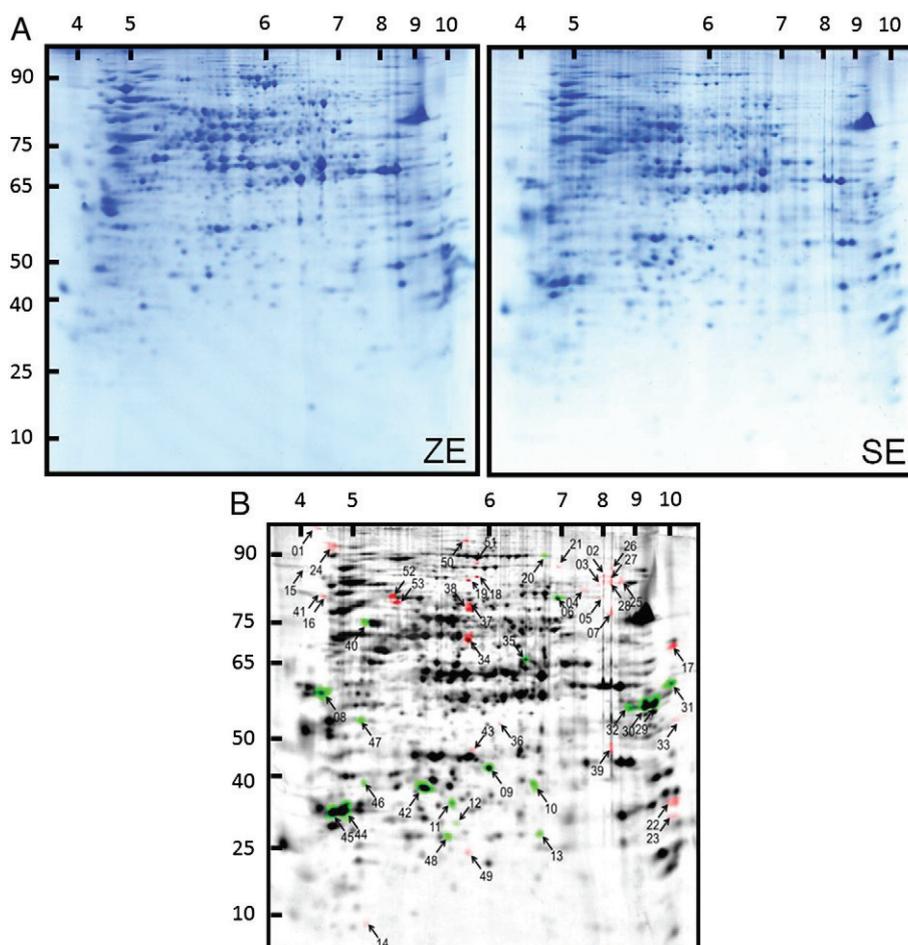

least 3-fold more abundant in the zygotic embryo proteome, whereas 20 protein spots were at least 3-fold higher in abundance in the somatic embryo proteome (Fig. 2B).

#### 3.2. Protein identification

Protein spots of at least 3-fold higher abundance in one or the other type of embryo were used for protein identifications by mass spectrometry (53 distinct spots). For 32 spots, protein identifications were successful (58%). Cacao is a non-model plant; its genome has just been described [45]. Hence, only a limited number of cacao proteins have been correctly annotated up to date. Table 1 shows proteins of increased abundance in the zygotic embryo proteomes. Those of increased abundance in somatic embryo proteomes are presented in Table 2. Detailed information on MS parameters of each identified protein is given in Table 3 (supplementary material). Within the 32 protein spots successfully analyzed, 68 distinct proteins were identified, 30 of which belong to the SE proteomes and 38 to the ZE proteomes. Within 19 spots, more than one protein was identified. This indicates that proteins overlapped during electrophoretic separation (Table 3). Functional classification of the identified proteins, which was carried out in accordance to KEGG PATHWAY Database, allowed the distinction of seven functional categories: (1) carbohydrate metabolism, (2) energy metabolism, (3) amino acid metabolism, (4) genetic information processing, (5) cellular processes, (6) stress response and (7) defense. Within these functional categories, carbohydrate metabolism, genetic information processing and amino acid metabolism likewise were of significant dimension in both proteomes but represented by different proteins. Proteins of stress response and energy metabolism were of higher abundance in SE. Two protein species of an ABC transporter were of increased abundance in ZE proteomes. In both proteomes, three protein categories were especially important, which overall include 56% of all identified proteins. These categories are: genetic information processing (21 proteins [14 proteins in ZE and 7 in SE]), carbohydrate metabolism (11 proteins [6 proteins in ZE and 5 in SE]) and stress response (7 proteins) (Table 1 and 2).

A few spots were found to include identical proteins. These proteins are considered to represent different protein species resulting from posttranslational modifications which introduce changes of molecular weight (MW) and/or isoelectric point (pI). Examples are a class III peroxidase (spots 29 and 31), ABC transporter E family member 2 (spots 2 and 25), trypsin inhibitor (spots 44 and 45), 21 kDa seed protein (spots 44 and 45) and phosphoglycerate dehydrogenase (spots 37 and 38).

Proteins involved in genetic information processing and carbohydrate metabolism represent 30 and 16% of the proteins which are of increased abundance in one of the two types of embryos. In the ZE proteome, except for sucrose synthase (spot 51), all other proteins are glycolytic enzymes: phosphoenolpyruvate carboxylase (spots 50), phosphoglucosyltransferase (spot 52), pyrophosphate-fructose 6-phosphate 1-phosphotransferase (spot 53), pyruvate decarboxylase isozyme 2-like (spot 52) and pyruvate kinase (spot 38) (Table 1). In the SE proteome, proteins of carbohydrate metabolism belong to different pathways such as (i) tricarboxylic acid cycle (1 protein), (ii) glyoxylate cycle (1 protein), (iii) pyruvate metabolism (2 proteins) and

**Fig. 2 – Proteome of *T. cacao* embryos. (A) IEF-SDS PAGE of total soluble protein fractions extracted from 100 mg fresh embryo tissue. Molecular masses range from 5 to 100 kDa are given on the left side. Isoelectric points, pI 3–11 are given above the gel image. Gels were stained with CBB-G 250. ZE=Zygotic embryos. SE=Somatic embryos. (B) Overlay image of IEF-SDS PAGE of zygotic and somatic embryo proteomes using the DELTA 2D software. Red-labeled spots were at least 3-fold more abundant in zygotic embryos and green-labeled spots were at least 3-fold more abundant in somatic embryos.**

(iv) ascorbate metabolism (1 protein) (Table 2). Five proteins in the zygotic embryo proteome were considered of special interest regarding their physiological function. These proteins are phosphoenolpyruvate carboxylase (spot 50), sucrose synthase (spot 51), aspartic proteinase (spot 17), ubiquitin (spot 50) and histone H2A (spot 22). They were respectively 4.82, 4.02, 3.04, 4.82 and 8.04 fold more abundant than in SE proteomes. In the SE proteome, besides proteins involved in carbohydrate metabolism and genetic information processing, stress related proteins were of special abundance (7 proteins). Another interesting finding within the SE proteome was the relatively high abundance of a trypsin inhibitor found in spots 44 and 45. These two proteins species were 9.67 and 3.84 fold more abundant than in the ZE proteome.

#### 4. Discussion

*T. cacao*, due to its allogamous status [6], requires an efficient vegetative propagation system. Somatic embryogenesis was

reported the first time in the study of Esan 1975 [46]. It then has been improved successively over the two last decades [7,11,12]. Currently, this clonal technique is considered to represent a prominent in vitro regeneration system for cacao. Several advantages are associated with this technique such as multiplication of elite genotypes, mass propagation [12] and the development of genetic transformation systems [47]. Unfortunately, the complexity of this developmental system and the numerous unknown factors that control it discouraged its systematical exploration. The current limitation encountered with this propagation system especially is the poor plantlet growth and low survival rate after transplanting [48]. Proteomics, which nowadays became a powerful biochemical technique to unravel in depth physiological processes, has been applied to embryogenesis in several plant systems [25,26,28–30,49]. These studies led to valuable information. In this study, we applied a comparative proteomic approach to describe physiological differences between zygotic and somatic embryos that may explain the poor development of plantlets derived from somatic embryogenesis in *T. cacao*. Three independent electrophoresis runs from

either SE or ZE material enabled the resolution of about 1000 protein spots. The analysis of scanned gels confirmed the reproducibility of the experiments. Several proteins were found to be of differential abundance between ZE and SE including enzymes involved in protein folding processes. Enzymes of special interest are discussed in the following sections.

#### 4.1. Carbohydrate metabolism, the backbone physiological pathway in embryogenesis

Zygotic and somatic embryos both highly accumulate enzymes of carbohydrate metabolism. Only one enzyme involved in sucrose metabolism, sucrose synthase (spot 51), was found in the frame of the current study. The other

<sup>b</sup> Functional protein classification according to the KEGG PATHWAY Database. Additional categories are included when necessary.

<sup>c</sup> Protein spot abundance: statistically significant values of at least 3 fold more abundant protein spots are given for the somatic embryos proteomes (relative spot volume SE/relative spot volume ZE). These protein spots are given in green on Fig. 2B.

<sup>d</sup> Spot ID as given on Fig. 2B.

proteins of this functional category are involved in energy metabolism (glycolysis, TCA cycle, glyoxylate cycle). Indeed, embryogenesis is a complex developmental process which is extensively based on carbohydrate metabolism (including sugar conversion), as previously reported in *Picea marina*, *P. glauca* [50], *C. persicum* [26,28,29] and in *P. dactylifera* [30]. The explanation for extensive carbohydrate metabolism is the heavy energy demand required for metabolic processes that occur during cell division and elongation.

In this study, although carbohydrate and energy metabolism was expressed in both types of embryos investigated, a clear change in specific protein abundance was observed. In the course of our investigation, glycolytic proteins were found of higher abundance in ZE while SE proteomes included higher abundance of proteins involved in other metabolic pathways of carbohydrate metabolism such as lactoylglutathione lyase (spot 46, 47), malate synthase (spot 6), a putative L-galactose-1-phosphate phosphatase (spot 47) and malate dehydrogenase (spot 32). The latter protein, which belongs to the tricarboxylic acid (TCA) cycle, is one of the most abundant proteins found in SE proteomes. It was

found to be of 46.02 fold higher abundance than in ZE proteomes. Furthermore, oxidative phosphorylation, represented by NADH-ubiquinone oxidoreductase (spots 11), ATP synthase (spot 40) and flavoprotein wrbA (spot 45) were 3.84, 3.79 and 4 fold more abundant in SE, indicating that these embryos undergo extensive oxidation processes. The higher level of TCA cycle and oxidative phosphorylation enzymes in SE suggests a more active aerobic/respiration pathway. This intensive energy metabolism might be the reason for the absence of dormancy (common feature of SE) as previously suggested by Sghaier-Hammami et al. [30]. Moreover, increased accumulation of pyruvate decarboxylase in ZE (PDC; EC 4.1.1.1; spot 52), which catalyzes the decarboxylation of pyruvate to acetaldehyde in the frame of an ethanol fermentation pathway [51], reinforces ideas of anaerobic fermentation as the major energy pathway in ZE. This might be the consequence of limited oxygen availability for the ZE, which is surrounded by seed coat and endosperm. Furthermore, the high abundance of malate synthase (spot 32) in SE, which represents a marker of beta-oxidation and which normally takes place in seed germination [52,53], indicates

the breakdown of lipid compounds. This finding reinforces the idea of a high energy demand in SE. Furthermore, it reveals involvement of lipid compounds as energy supplier in cacao embryos. Interestingly, these observations demonstrate that, compared to their zygotic counterpart, SE of *T. cacao* may undergo precocious mobilization of storage compounds which might be the reason for the less vigor of derived plantlets compared to those originating from ZE. An earlier study carried out on globulin mobilization in SE of *Elaeis guineensis* resulted in a similar conclusion [54].

Phosphoenolpyruvate carboxylase (PEPC; EC 4.1.1.31) is found in increased abundance in ZE. This glycolytic protein is a CO<sub>2</sub>-fixing enzyme that catalyzes the irreversible  $\beta$ -carboxylation of phosphoenolpyruvate (PEP) in the presence of HCO<sub>3</sub><sup>-</sup> and Mg<sup>2+</sup> to yield oxaloacetate (OAA) and inorganic phosphorus (Pi) [55]. In earlier studies, this enzyme was only related to photosynthesis but, over the last decade, a growing number of studies revealed that, under non-photosynthesis conditions, especially in seeds, PEPC re-fixes HCO<sub>3</sub><sup>-</sup> liberated by respiration and, together with PEP, yield oxaloacetate that can be converted to aspartate, malate or other intermediates of the TCA cycle [56–58]. Thus, this metabolic pathway maintains the pool of carbon residues necessary for the biosynthesis of oil and storage proteins that take place in later stage of embryo development [59–61]. Intriguingly, the consistent accumulation of PEPC in cacao embryos raises the question of the role of this enzyme in cacao seed maturation and germination which, according to its high lipid content, might display an extensive PEPC activity as demonstrated with castor oilseed [62,63].

Sucrose synthase (SuSy, EC 2.4.1.13; spot 51 in Fig. 2B) is the only enzyme of sugar metabolism found in the frame of our study. This enzyme was 4.02 fold higher in abundance in ZE proteomes. SuSy is a cytoplasmic enzyme that catalyzes the reversible break down of sucrose. This enzyme has been studied by several research groups and has been associated with a broad range of physiological functions mostly related to carbohydrate metabolism [64,65]. Iraqi and Tremblay [50] suggested that this enzyme catalyzes the synthesis of sucrose from glucose and fructose in order to maintain the optimal sucrose level in plant tissues during embryo maturation. Other studies reported its involvement in starch and cell wall synthesis [66]. The low abundance of SuSy in SE suggests a possible disturbance in carbohydrate metabolism that might result in irregularities in storage compound and cell wall metabolism.

#### 4.2. High abundance of stress related proteins in somatic embryos of *T. cacao*

In the frame of our study, stress induced proteins were found in higher abundance in SE proteomes where they represented the dominant group of proteins (more than 23% of the total proteins classified as more abundant in SE [Table 2]). The most representative proteins among this group were peroxidases (spots 29, 31, 32 and 35), pathogenesis related protein (spot 42) and glutathione S-transferase (GSTs) (spot 9). This observation is in accordance with the one of Rode et al. 2011 [28] who noticed that SE of *C. persicum* were more stressed than their ZE counterpart. Indeed, somatic cells of plants require a number of stress factors to switch their developmental program to a

specific physiological state that allows the reprogramming of gene expression towards acquisition of embryonic competence [67–70]. In *T. cacao*, a set of stress factors encompassing wounding, salt component (MgSO<sub>4</sub>) and several growth regulators (TDZ, 2,4-D and Kinetin) are required to turn somatic cells of floral explant into competent embryonic callus cultures [7,8,11]. Among plant growth regulators of auxin family, 2,4-D is especially recognized as oxidative stress inducer [67,68,71]. For instance, GSTs which appear in increased abundance in SE proteomes in this study have been earlier described as auxin-induced proteins involved in the acquisition of cellular totipotency during somatic embryogenesis [68,71]. Further explanations for this extensive activity of oxidative stress enzymes come from oxidative phosphorylation described in the previous section. Indeed, oxidative phosphorylation is the source of reactive hydrogen, a poisonous compound for plant tissues. Peroxidases and GSTs, which are endowed with xenobiotic functions [72,73], are of great importance for eliminating H<sub>2</sub>O<sub>2</sub> resulting from oxidative phosphorylation.

#### 4.3. Aspartic proteinase, dominant enzyme in protein mobilization in *T. cacao* embryo

Aspartic proteinase precursor (spot 17) was found 3.04 fold more abundant in ZE proteomes. This enzyme represents the only protein involved in a catabolic pathway, which was of increased abundance in this study. Aspartic proteinase (EC 3.4.23) is the dominant endopeptidase component involved in storage protein processing found in cacao seeds [74]. In addition, this enzyme was found to be exceptionally more active in cacao seeds than in seeds of other plant species [75]. Regarding the crucial role of this enzyme, which is responsible for the initial breakdown of proteins during germination [15,76], its relatively early accumulation in ZE in the torpedo stage, might be an indication of the onset of maturation which did not take place in SE.

#### 4.4. Exceptional high accumulation of endopeptidase inhibitor in somatic embryos

In contrast to the active protein biosynthesis and the significant accumulation of aspartic proteinase precursor noticed in ZE, SE highly accumulate peptidase inhibitors. Indeed, two types of endopeptidase inhibitors were found in high abundance in SE proteomes. From a total of four protein species identified as members of this family, two belonged to the group of trypsin inhibitors while the two others were identified as 21 kDa seed proteins. The latter was also described as homolog of soybean trypsin inhibitor [77]. Thus, all these endopeptidase inhibitors can be considered as trypsin inhibitors. Trypsin inhibitor has been earlier reported in *Daucus carota* to be associated with somatic embryogenesis [78]. Unfortunately, no biological function of this enzyme related to somatic embryogenesis has been established yet. Recently, Guilloteau et al. [76] found trypsin inhibitor to be part of an active aspartic proteinase complex in cacao seeds. They suggested this trypsin inhibitor sub-unit to protect storage proteins from precocious hydrolysis that might result from the high aspartic proteinase content in cacao seeds.

Nevertheless, the role of this enzyme in cacao seeds remains far from being elucidated.

#### 4.5. Differences in protein folding processes in zygotic and somatic embryos

Ubiquitin (spot 50) and T complex protein (spot 53) are the two proteins of increased abundance found in our experimental system to be involved with protein folding processes. They appeared in ZE proteomes and they were respectively 4.82 and 3.71 fold more abundant than in SE proteomes. Ubiquitin has been previously described as a biochemical tag endowed with the capacity to link covalently with other proteins for degradation and refolding of proteins [79]. The low accumulation of this protein in SE proteomes suggests a possible disturbance on protein folding in these embryos. On the other hand, T complex protein is a protein binding component whose physiological role is not yet clearly elucidated. However, it has been described as a binding factor that transfers DNA fragments from *Agrobacterium tumefaciens* into plant nucleus [80]. Recently, Hurov et al. [81] reported the intervention of proteins belonging to T complex family in protecting cells from spontaneous DNA damage. The high abundance of T complex protein in ZE proteomes suggests the involvement of this protein in a specific pathway important in embryo development in *T. cacao*. Furthermore, due to its presumable involvement in protecting DNA from damage, this protein, which might not be sufficiently accumulated in SE, might cause susceptibility of DNA in this type of embryo and therefore explain the cause of somaclonal variations that frequently occur during somatic embryogenesis. The increased accumulation of histones (histone H2A and histone H2B; spot 22) that both were 8.04 fold higher in abundance in ZE proteomes, corroborate this view because of their participation in DNA integrity.

#### 5. Concluding remarks

The data presented here clearly demonstrate the efficiency of MS-based proteomic investigations in describing in depth physiological processes. The comparison between SE and ZE proteomes come-up with new insights into embryogenesis of *T. cacao*. The absence of dormancy and the occurrence of somaclonal variations, current features of somatic embryogenesis, have been connected to changes in specific proteins abundances. Furthermore, the consequences of the exposure of plant material to stress factors during this specific developmental process have been described. Trypsin inhibitor, whose function in seed biology is not yet clearly understood, appeared in this study to be intrinsically associated with somatic embryogenesis in *T. cacao*. ZE proteomes revealed the importance of aspartic proteinase, phosphoenolpyruvate carboxylase and sucrose synthase in *T. cacao* embryogenesis. The most pronounced difference among the two types of embryos concerns carbohydrate metabolism: ZE proteomes display a high glycolytic activity while SE are characterized by intensive aerobic/respiration pathway activity as documented by the exceptional increased of TCA cycle proteins as well as proteins

of oxidative phosphorylation. Thus, regarding these specific physiological features, somatic embryogenesis, which is an induced developmental process, is driven by an adapted metabolism. These new findings shed light to the procedure of inducing SE.

Both types of embryos were harvested in similar morphological shapes; however their developmental stages might have been slightly different. Thus, it cannot be excluded that some of the observed differences in protein abundances were related to this developmental variation. Further proteomic approaches should therefore also include series of zygotic and somatic embryo stages.

Finally, a large number of uncharacterized proteins have also been found in this study (Table 3; supplementary material). The reason for this fact is the poor availability of cacao proteins in databases. Although the cacao genome has recently been sequenced, there is still a great need for protein characterization in this plant species.

### **Abstract**

Amino acid catabolism is essential for adjusting pool sizes of free amino acids and takes part in energy production as well as nutrient remobilization. The carbon skeletons are generally converted to precursors or intermediates of the tricarboxylic acid cycle. In the case of cysteine, the reduced sulfur derived from the thiol group also has to be oxidized in order to prevent accumulation of toxic concentrations. Here we present a mitochondrial sulfur catabolic pathway catalyzing complete oxidation of L-cysteine to pyruvate and thiosulfate. After transamination to 3-mercaptopyruvate the sulfhydryl group from L-cysteine is transferred to glutathione by sulfurtransferase 1 and oxidized to sulfite by the sulfur dioxygenase ETHE1. Sulfite is then converted to thiosulfate by addition of a second persulfide group by sulfurtransferase 1. This pathway is most relevant during early embryo development and for vegetative growth under light limiting conditions. Characterization of a double mutant produced from *Arabidopsis thaliana* T-DNA insertion lines for ETHE1 and sulfurtransferase 1 revealed that a persulfide intermediate interferes with amino acid catabolism and induces early senescence.

### **Introduction**

Amino acid catabolism in plants is involved in the regulation of steady state levels of free amino acids and is particularly important in conditions of increased protein turnover such as germination and senescence. It is critical for nutrient redistribution from senescing leaves to newly formed sink organs such as young leaves and developing seeds. The degradation of amino acids also contributes to energy production in situations of carbohydrate starvation, which may occur during drought or unfavorable light conditions. Pool sizes of free amino

acids are highly diverse and dynamically change in response to environmental or developmental factors (Hildebrandt et al. 2015). However, the intracellular concentration of cysteine is amongst the lowest known for protein amino acids. The thiol group of cysteine is highly reactive, it can deplete cells of pyridoxal phosphate by forming thiazolidine derivatives and in addition autooxidation in the presence of transition metals generates reactive oxygen species (Osman et al. 1997). Therefore, intercellular concentrations have to be tightly controlled in order to avoid toxic effects. However, cysteine levels also must be sufficiently high to support protein synthesis and the production of other essential molecules such as glutathione, coenzyme A and reduced sulfur for the biosynthesis of iron sulfur clusters, biotin, thiamin, and molybdenum cofactor (Balk and Pilon 2011, Van Hoewyk et al. 2008). Thus, synthesis as well as the degradation of cysteine has to be tightly regulated.

During degradation, the carbon skeleton of cysteine is converted to pyruvate via removal of the amino and sulfhydryl group. These reactions can be catalyzed by different pathways. Cysteine desulfhydrases deaminate cysteine to pyruvate, ammonia, and hydrogen sulfide ( $H_2S$ ). Specific isoforms using L-Cys (DES1, EC 4.4.1.1) and D-Cys (D-CDES, EC 4.4.1.15) as a substrate are present in the cytosol and the mitochondrial matrix, respectively (Alvarez et al. 2010, Riemenschneider et al. 2005). Both enzymes are induced during senescence and therefore have been implicated in cysteine catabolism for nutrient remobilization. DES1 deficient *Arabidopsis* mutants accumulate cysteine and in addition show alterations in autophagosome formation and stomatal opening, which are reversible by supplementation with  $H_2S$  (Alvarez et al. 2010, 2012, Jin et al. 2013). Taken together, these results demonstrate that the desulfhydration reaction is relevant for cysteine homeostasis and also regulates production of the signaling molecule  $H_2S$ . However, the further fate of  $H_2S$ , which is highly toxic already at low micromolar concentrations, has not been analyzed yet. Cysteine desulfurases (NifS-like proteins, EC 2.8.1.7) provide sulfur for the synthesis of iron-sulfur clusters, biotin, and thiamin (Couturier et al. 2013).

We recently demonstrated a role of the sulfur dioxygenase ETHE1 (EC 1.13.11.18) in plant cysteine catabolism (Krübel et al. 2014). ETHE1 is localized in the mitochondrial matrix and oxidizes glutathione persulfide (GSSH) to sulfite. Knockout of the ETHE1 gene (AT1G53580) in *Arabidopsis* leads to an arrest of embryo development at early heart stage (Holdorf et al. 2012). Knockdown mutants are viable but show a delay in embryo development (Krübel et al. 2014). Interestingly, ETHE1 is highly induced by carbohydrate

starvation and mutants develop premature leaf senescence under light limiting growth conditions indicating a role in the use of amino acids as alternative energy source.

Here we present the additional steps of the ETHE1 dependent mitochondrial sulfur catabolic pathway catalyzing complete oxidation of L-cysteine to pyruvate and thiosulfate. After transamination to 3-mercaptopyruvate the sulfhydryl group from L-cysteine is transferred to glutathione by sulfurtransferase 1. Interestingly, this enzyme also converts sulfite to the final product thiosulfate by addition of a second persulfide group.

Sulfurtransferases catalyze the transfer of a sulfur atom from a suitable sulfur donor to nucleophilic sulfur acceptors. 20 putative sulfurtransferase isoforms are annotated in the *Arabidopsis* genome and some of them have already been characterized on a protein basis (Bartels et al. 2007). They might play a role in plant development and stress response, however, the exact function has not been identified yet. *In vitro*, the activity is measured using either thiosulfate or 3-mercaptopyruvate as a sulfur donor and cyanide as an acceptor. Mao et al. (2011) recently demonstrated that the mitochondrial sulfurtransferase Str1 (AT1G79230) contributes the main mercaptopyruvate sulfurtransferase activity (about 80 %) in *Arabidopsis*. Knockout plants had no visible phenotype under long-day growth conditions, but seed development was severely compromised. The majority of seeds were shrunken and not able to germinate. Embryo development arrested at the heart stage producing abnormal morphological shapes and eventually aborted.

In order to identify the role of mitochondrial cysteine catabolism and the individual reaction steps in seed development as well as plant energy metabolism, we produced and characterized a double mutant from the ETHE1 knockdown line *ethe1-1* (Krübel et al. 2014) and the Str1 knockout line *str1-1* (Mao et al. 2011).

## Materials and methods

### *Plant material and growth conditions*

All *Arabidopsis thaliana* plants used for this study were of the Columbia ecotype (Col-O). Plants were grown in climate chambers under long-day conditions (16h light/8h dark) or short-day conditions (8h light/16h dark) at 22 °C, 85  $\mu\text{mol s}^{-1} \text{m}^{-2}$  light and 65 % humidity. The T-DNA insertion line SALK\_021573 (*ethe1-1*) for the gene AT1G53580 has been

characterized in our lab before (Krübel et al. 2014). Seeds of the line SALK\_015593 (*str1-1*) for the gene AT1G79230 were obtained from the Nottingham *Arabidopsis* Stock Centre (University of Nottingham, UK). This line has been described by Mao et al. (2011). The *ethe1-1* x *str1-1* double mutant was produced by crossing of the two T-DNA insertion lines described above. Homozygous mutant lines were identified by genomic PCR using gene-specific primers (5'-TGGAATTGGGTTATATGGTGG-3' and 5'-CGGATCAATCAACTGCTCATC-3' for *ethe1-1* and 5'-AAAGGGGATCTTTAGTGCAGC-3' and 5'-GTGGGAAGGAAGCAAATTCTC-3' for *str1-1*) and the T-DNA left border primer LBb1.3 (5'-ATTTTGCCGATTCGGAAC-3'). Complete rosettes of wild type and mutant plants were harvested at dawn and used for metabolite analysis.

#### *Expression and purification of ETHE1 and Str1*

Expression and purification of recombinant ETHE1 protein was performed like described before (Krübel et al. 2014). The plasmid containing *Arabidopsis* Str1 was generously provided by Jutta Papenbrock (Institute for Botany, Leibniz University Hannover) and expressed in the same way as ETHE1.

#### *Cell suspension cultures and isolation of mitochondria*

*Arabidopsis* cell suspension cultures were established and maintained as described by May and Leaver (1993) and Sunderhaus et al. (2006). Mitochondria were prepared following to the procedure outlined by Werhahn et al. (2001).

#### *Sulfur dioxygenase activity test*

SDO activity was measured at 25°C in a Clarke-type oxygen electrode (Oroboros Oxygraph and Hansatech DW1 Oxygraphy) following the procedure described in Hildebrandt and Grieshaber (2008). The reaction contained 1 to 2 µg/ml purified enzyme or 150 to 300 µg/ml mitochondrial protein in 0.1 M potassium phosphate buffer pH 7.4. For the standard activity test, 1 mM GSH (final concentration) was added, followed by 15 µl/ml of a saturated elemental sulfur solution in acetone. Acetone did not inhibit enzyme activity. Rates were

measured during the linear phase of oxygen depletion, which occurred in the first 2 to 3 minutes.

### *Phenotype analysis*

For general phenotype analysis a modified version of the procedure described in Boyes et al. (2001) was used. Plants were grown under long-day or short-day conditions and growth parameters were measured once per week.

Embryo morphology was analyzed with a microscope equipped with Normarski optics. Seeds were dissected from the siliques and cleared in Hoyer's solution (15 ml distilled water, 3.75 g gum arabic, 2.5 ml glycerine, 50 g chloral hydrate) overnight before analysis.

Germination rates were determined for seeds of wild type, *ethe1-1* and three different morphological types of *str1-1* and *ethe1-1xstr1-1*. The seeds were surface sterilized with 6% sodium hypochloride and 100% ethanol followed by five washing steps with sterilized water. For vernalization seeds were incubated for 2 days at 4°C in the dark. Approximately 20 seeds were sown per plate (3 replicates per sample) on MS-medium without a carbon source and incubated for another 2 days at 4°C in the dark. Afterwards the plates were placed into a growth chamber (24°C, 16 h light/8 h dark). After 24, 48 and 72h germinated seeds were counted. A seed is considered to be germinated when the radicle ruptures the endosperm and the testa.

### *Metabolite analysis*

Products of the sulfur dioxygenase reaction were analyzed by HPLC (Hildebrandt and Grieshaber, 2008).

For metabolite profiling complete rosettes of wild type and mutant plants grown under short day conditions were harvested at the end of the dark period at the age of 42 days and 100 days. Metabolite analysis by GC-MS was performed essentially as described by Liseč et al. (2006) and by extracting of metabolites for injection of extracts from 1mg fresh weight of plant material into the GC/TOF-MS. Chromatograms and mass spectra were evaluated by using TagFinder 4.0 software (Luedemann et al. 2008) and Xcalibur 2.1 software (Thermo Fisher Scientific, Waltham, USA). Metabolites were identified in comparison to database entries of authentic standards (Kopka et al. 2005, Schauer et al. 2005). Peak areas of the mass

(m/z) fragments were normalized to the internal standard (ribitol) and fresh weight of the samples. Identification and annotation of detected peaks are shown in Supplemental Table S1 following recent recommendations for reporting metabolite data (Fernie et al. 2011).

## Results

### *Enzymatic steps of the mitochondrial cysteine catabolic pathway*

In a previous study we demonstrated that the mitochondrial sulfur dioxygenase ETHE1 oxidizes persulfide groups derived from 3-mercaptopyruvate to sulfite and postulated a role for this reaction sequence in L-cysteine catabolism (Krübel et al. 2014). In order to identify the complete pathway and provide evidence for the individual reaction steps (Fig. 1A), we measured sulfur dioxygenase activity in mitochondria after the addition of L-cysteine as a substrate (Fig. 1B) and in addition reconstituted part of the pathway with isolated recombinant enzymes (Fig. 1 C, D). Our results indicate that L-cysteine is oxidized by the ETHE1 pathway after transamination to 3-mercaptopyruvate. Mitochondrial oxygen consumption with L-cysteine as a substrate was detectable only if 2-oxoglutarate was included in the reaction mixture as an amino group acceptor for transamination. The activity was very low in the *ethe1-1* knockdown mutant showing that the oxygen consumption rate in wild type mitochondria was indeed specific for the ETHE1 dependent pathway (Fig. 1B).

Next, we tested whether ETHE1 in combination with the main mitochondrial sulfurtransferase Str1 is able to catalyze the remaining part of the postulated pathway, i.e. transfer of the sulfhydryl group from 3-mercaptopyruvate to glutathione, oxidation to sulfite, and addition of a second persulfide group to produce thiosulfate (Fig. 1A). Isolated recombinant ETHE1 enzyme oxidizes glutathione persulfide (GSSH), which is non-enzymatically produced from reduced glutathione (GSH) plus elemental sulfur (S<sub>8</sub>), to sulfite but cannot use the sulfhydryl group of 3-mercaptopyruvate as a substrate (left side of Fig. 1C and D). However, in the presence of isolated recombinant sulfurtransferase 1 protein, the sulfur dioxygenase activity is comparable with elemental sulfur or 3-mercaptopyruvate added as a substrate (right side of Fig. 1C). Thus, the sulfurtransferase is able to produce GSSH as a substrate for ETHE1 by transferring the sulfhydryl group of 3-mercaptopyruvate to GSH. Thiosulfate did not serve as a substrate for this reaction sequence (data not shown). Our results also provide evidence for a second function of Str1 in the cysteine catabolic pathway. The main product of persulfide

oxidation by ETHE1 in the presence of Str1 is thiosulfate, indicating that the sulfurtransferase adds an additional persulfide group to the sulfite produced by the sulfur dioxygenase reaction (left side of Fig. 1D).

#### *Physiological roles of mitochondrial cysteine catabolism*

Having identified the individual steps of mitochondrial cysteine catabolism we next addressed the physiological role of this reaction sequence during the *Arabidopsis* life cycle. T-DNA insertion lines for both, ETHE1 and Str1 have already been characterized (Holdorf et al. 2012, Krübel et al. 2014, Mao et al. 2011) and show different phenotypes. Therefore, in order to unravel the metabolic reason for the individual effects we produced a double mutant from the strong knockdown line *ethe1-1* (Krübel et al. 2014) and the knockout line *str1-1* (Mao et al. 2011).

#### *Seed and embryo development is severely impaired in the *ethe1-1 x str1-1* double mutant*

Since embryo development is effected in ETHE1 as well as Str1 deficient mutants, we first analyzed the seeds of the *ethe1-1 x str1-1* double mutant to see whether down-regulation of both enzymes had additive effects. In summary, embryo development of the double mutant was comparable to *str1-1* (Fig. 2). Wild type embryos developed very uniformly reaching the mature stage at seven days after pollination (DAP), whereas several growth stages were simultaneously present in *ethe1-1* siliques, and not until 10 DAP all of them were mature (Fig. 2B). In contrast, embryogenesis was severely delayed in *str1-1* and the *ethe1-1 x str1-1* double mutant. Most of the mutant embryos were still in the pre-globular or globular stage at 5 DAP when the wild type had already reached cotyledon stage (Fig. 2B). At 7 DAP wild type seeds were already dark green indicating that the embryos had developed their full photosynthetic capacity (Fig. 2A). In contrast, seeds of *str1-1* plants and the double mutant were smaller, of a white, light green or even light brown color, and contained embryos in the globular to cotyledon stage. Starting from about 10 DAP different degrees of a brown, shriveled seed phenotype became apparent (Fig. 2A, Supp Figs. S1 and S2). Embryos developed morphological abnormalities such as giant heart stage or asymmetric cotyledons (Fig. 2A, Supp Figs. S3 and S4). Less than 50 % of the *str1-1* and *ethe1-1 x str1-1* embryos finally reached the mature stage whereas the rest aborted mainly at heart stage.

While mature *ethe1-1* seeds were morphologically indistinguishable from the wild type, only about one fifth of the seeds from *str1-1* plants and the double mutant appeared normal. The rest of the seeds were to about equal parts of a rectangular shape or severely shrunken (Fig. 3). Germination was slightly delayed in *ethe1-1* with  $82 \pm 3$  % germinated seeds after 24 h compared to  $93 \pm 8$  % in the wild type (Fig. 3). However, already after 48 h there was no significant difference between germination rates of *ethe1-1* and wild type seeds. In contrast, the germination capacity of *str1-1* seeds was severely compromised. Even normal looking seeds were not completely germinated after 72 h, and in rectangular and shriveled seeds rates dropped to  $43 \pm 8$  % and  $20 \pm 5$  % respectively. Interestingly, seeds of the double mutant germinated significantly better than those of the *str1-1* mutant (marked by crosses in Fig. 3). The normal looking seeds behaved like *ethe1-1* seeds and also higher percentages of the misshaped seeds compared to the *str1-1* mutant were able to germinate ( $63 \pm 10$  % of rectangular and  $35 \pm 5$  % of shriveled seeds).

#### *Patterns of early leaf senescence under light limitation*

When grown under long-day conditions (16h light/8h dark) the phenotype of the three analyzed mutant lines was comparable to the wild type (Supp Fig S5). Shortening of the light period to 8 hours per day led to reduced growth and early leaf senescence in *ethe1-1* plants as described before (Krüßel et al. 2014), whereas the *str1-1* plants were indistinguishable from the wild type (Fig. 4). While development proceeded very uniformly in the wild type as well as in both individual mutant lines, the phenotype of the *ethe1-1 x str1-1* double mutant was diverse. Growth rates of the nine double mutant plants analyzed differed by a factor of 5 between  $0.6$  and  $3 \text{ mm} \cdot \text{day}^{-1}$  (Fig. 4A inserted graph). Plants number 3, 4, 6, 7, and 8 grew fast and were indistinguishable from the wild type until 10 weeks after sowing. Then, leaves progressively developed chlorotic patches in two of the large plants (number 4 and 6). In contrast, growth rates of 4 double mutant plants (number 1, 2, 5, and 9) were reduced in a similar way as in *ethe1-1*. However, only two of these small plants (number 2 and 5) started to become chlorotic after seven weeks of growth while the other two (number 1 and 9) remained dark green until leaves were harvested at the age of 100 days.

In order to identify the metabolic reason for these phenotype variations we analyzed metabolite profiles of wild type and mutant plants grown under short-day conditions (Supp. Tab. S2). Samples were harvested immediately after the dark period at two different

developmental stages: After 42 days neither wild type nor mutant plants showed any visible signs of senescence (“young plants” Supp. Fig. S6). However, *ethe1-1* rosettes were significantly smaller than the wild type ( $6.0 \pm 0.8$  compared to  $9.3 \pm 0.9$  cm) and contained less leaves ( $18.7 \pm 1.2$  vs.  $23.9 \pm 2.5$ ). The rosette diameter of *ethe1-1 x str1-1* double mutants varied between 1.6 and 8.5 cm, and small as well as big plants were used for the metabolite analysis. The second set of leaf samples was harvested after 100 days (“old plants”; Fig. 4B), when all plants had already started flowering. *Ethe1-1* leaves were about 50 % chlorotic and the double mutant displayed the four different phenotypes described above (see Fig. 4B), with an *ethe1-1*-like phenotype (plants 2 and 5), a wild-type-like phenotype (plants 3, 7, and 8), and two intermediate forms, i.e. small green plants (plants 1 and 9), and large plants with yellowing leaves (plants 4 and 6).

Already in the young plants harvested at 42 days after sowing a number of specific changes in the metabolite profiles of the mutants compared to the wild type became apparent (Figs. 5 and 6, Supp Tab S2). Nitrogen-rich amino acids accumulated in all mutants, and the concentrations of secondary metabolites involved in nitrogen turnover such as putrescine and spermidine were also significantly increased (Fig. 5A; upper panel). In addition, we detected significantly higher concentrations of the amino acids taking part in photorespiration, glycine and serine, in *str1-1* and the double mutant (Fig. 5C). Interestingly, serine was also elevated in *ethe1-1* plants without the concomitant increase in glycine leading to a significant decrease of the glycine/serine ratio, which is often used as an indicator of photorespiratory activity. Specific effects on the TCA cycle also became apparent. In all three mutants succinate and fumarate concentrations were significantly lower than in the wild type (1.9 to 6.5fold), and malate was additionally decreased in *str1-1* and the double mutant (Fig. 6).

The metabolite profile of young *ethe1-1* plants revealed two characteristic changes that were not present in *str1-1* or the double mutant. There was a significant increase in the amino acids associated with energy metabolism, i.e. branched-chain amino acids, lysine, and aromatic amino acids (Fig. 5B, upper panel). In addition, carbohydrate metabolism was effected with a strong accumulation of galactinol (5.3fold) and raffinose (8fold) and lower but still significant increases in sucrose and fructose concentrations while glucose was slightly decreased (Fig. 6). Metabolite profiles of the old plants harvested 100 days after sowing reflected patterns typical for leaf senescence. In particular, a general increase relative to the young plants in concentrations of free amino acids most pronounced in those involved in nitrogen

remobilization, a strong decrease in the glycine/serine ratio, and an accumulation of sugars were detected in wild type as well as mutant plants (Figs. 5 and 6).

Next, we analyzed the metabolite profiles of the individual plants using the hierarchical clustering tool available in MeV (Fig. 7). The metabolite profile of *str1-1* was very similar to the wild type in the old plants so that the clustering algorithm was not able to distinguish between these two groups. However, all five *ethe1-1* plants were clearly grouped together on the basis of their metabolite profiles and, most interestingly, 8 of the 9 *ethe1-1 x str1-1* plants clustered correctly according to their phenotype. The small and chlorotic double mutant plants (number 2 and 5), which looked like *ethe1-1* plants of the same age, also had the most similar metabolite profiles followed by the big plants with chlorotic leaves (number 6 and 7). Four of the five double mutant plants that were still entirely green at the time of harvest clustered together, and again profiles of the small rosettes (number 1 and 9) were clearly separated from those of the big rosettes (number 7 and 8). Only one of the double mutant plants with no visible phenotype (number 3) was mixed up with the wild type and *str1-1* plants. Since not only the plants but also the metabolites were clustered it was possible to derive patterns typical for the individual phenotypes (marked by the black boxes in Fig. 7). A strong accumulation of galactinol and raffinose was present only in plants with the *ethe1-1* phenotype, while sugar levels in general were decreased compared to the wild type in *ethe1-1* as well as all double mutant plants (see also Fig. 6). Concentrations of urea as well as the amino acids and metabolites associated with nitrogen remobilization were low in all plants with small rosettes (see also Fig. 5A, lower panel). Features characteristic for plants with chlorotic leaves were an increase of serine and glycine concentrations, a decrease in ascorbate and dehydroascorbate content, and specific changes in TCA cycle intermediates with a relative increase in citrate and 2-oxoglutarate and a decrease in succinate and fumarate (see also Fig. 6). Proline and alanine accumulated in all *ethe1-1* and double mutant plants compared to the wild type and *str1-1*.

## Discussion

We identified a mitochondrial cysteine catabolic pathway and revealed the physiological relevance of individual reaction steps for seed development and plant growth under limited light conditions.

### *Three mitochondrial enzymes oxidize L-cysteine to pyruvate and thiosulfate*

Our results show that L-cysteine can be transaminated to 3-mercaptopyruvate in *Arabidopsis* mitochondria. Subsequently, the thiol group is transferred to GSH by sulfurtransferase 1, oxidized to sulfite by the sulfur dioxygenase ETHE1 and transferred to an additional persulfide to produce thiosulfate by sulfurtransferase 1. A similar reaction sequence has been described in animal mitochondria (Hildebrandt and Grieshaber 2008). However, persulfide groups are derived from the oxidation of hydrogen sulfide catalyzed by sulfide:quinone oxidoreductase, which is not present in plants.

### *A cysteine aminotransferase is present in Arabidopsis mitochondria*

The protein catalyzing the initial transamination step of the cysteine degradation pathway has not been identified so far, and no cysteine aminotransferase is annotated in the *Arabidopsis* genome. The same activity has been found in animal mitochondria and postulated to be an additional function of an aspartate aminotransferase (Ubuka et al. 1978). 31 aminotransferases with different substrate specificities have been described in *Arabidopsis* so far, and 10 of them are probably localized in the mitochondrial matrix (Hildebrandt et al. 2015). These mitochondrial aminotransferases are annotated to be specific for ornithine, aspartate, branched-chain amino acids, alanine, and glyoxylate, and it will be the subject of future studies to find out whether one of them or an additional enzyme not identified as an aminotransferase so far catalyzes the transamination of L-cysteine.

### *Two physiological roles for plant mitochondrial sulfurtransferase*

Sulfurtransferases are ubiquitous enzymes present in all the different compartments of plant, animal and also prokaryotic cells. However, their metabolic functions have not been completely understood yet. The detoxification of cyanide has initially been considered to be

the main role of sulfurtransferases since cyanide is a very good acceptor for persulfide groups *in vitro* and sulfur addition converts it to less toxic thiocyanate (Westley 1973). In plants, cyanide is produced in equimolar amounts during the biosynthesis of the hormone ethylene (Peiser et al. 1984). However, most of it is metabolized to asparagine via  $\beta$ -cyanoalanine, and the contribution of sulfurtransferases to cyanide detoxification seems to be rather low (Machingura et al. 2014, Meyer et al. 2003). Additional physiologically relevant functions of sulfurtransferases might be control of the sulfane sulfur pool, maintenance of iron–sulfur clusters, and molybdenum cofactor synthesis (Matthies et al. 2004, Ogata and Volini 1990, Westley et al. 1983). Here we demonstrate that the mitochondrial sulfurtransferase Str1 is part of a cysteine catabolic pathway in *Arabidopsis* and even catalyzes two of the four reaction steps. In the *in vitro* assay using cyanide as a sulfur acceptor Str1 has a higher activity with 3-mercaptopyruvate than with thiosulfate as a substrate and is therefore called mercaptopyruvate sulfurtransferase (Papenbrock and Schmidt 2000). In accordance with this result, we found that Str1 readily transfers the thiol group from 3-mercaptopyruvate but not from thiosulfate to GSH to produce GSSH as a substrate for the sulfur dioxygenase reaction. As already described in animals, sulfurtransferases can also produce thiosulfate by transferring a persulfide group from a suitable donor such as GSSH to sulfite (Hildebrandt and Grieshaber 2008). We detected the same activity in *Arabidopsis* Str1 representing the final step in mitochondrial L-cysteine degradation.

*Cysteine degradation and additional persulfide transfer reactions are essential during embryo development*

Complete knockout of either sulfurtransferase 1 or ETHE1 in *Arabidopsis* severely affects embryo development indicating that cysteine catabolism is highly important during this developmental stage. The reason for the seed defects could either be accumulation of a toxic intermediate or nutrient deficiency. Since both mutant lines are affected, the potential toxic intermediate is most likely produced prior to the first transsulfuration step, i.e. it might be 3-mercaptopyruvate, L-cysteine or the dimer L-cystine, which forms non-enzymatically from oxidized cysteine but, at least in animals, is supposed to be less toxic (Baker 2006). An alternative explanation would be the presence of two independent toxic intermediates in the individual mutant lines, since the sulfurtransferase probably has additional functions to its role in cysteine degradation such as cyanide detoxification. The seed phenotype of *ethe1-1 x str1-1* plants resembled the *str1-1* single mutant and was not worsened but in contrast even slightly

improved by the additional down-regulation of sulfur dioxygenase activity. This result would be in agreement with the postulated accumulation of toxic cyanide due to Str1 knockout and toxic persulfide due to ETHE1 knockdown. Persulfide accumulation is most likely reduced in the double mutant since the sulfurtransferase producing it is missing. In addition, residual persulfides potentially resulting from other reactions would readily react with cyanide and thus lessen the toxic effect.

As heterotrophic organs seeds depend on nutrient supply by the mother plant. Carbon is imported as sucrose, which is also the main substrate for energy production in the developing seed. Nitrogen is derived from remobilization of amino acids by protein degradation in the senescing leaves and mainly transported as glutamine and asparagine (Masclaux-Daubresse et al. 2010). It is currently not clear, whether the degradation of amino acids other than glutamine and asparagine substantially contributes to the nutrition of the developing embryo, and knowledge on the general role of amino acid catabolism in seeds is very limited. However, there is some evidence indicating that amino acids, analogous to the situation in starving leaves, can serve as alternative respiratory substrates to generate energy (Galili et al. 2014). Knockdown of ETHE1 leads to an accumulation of most amino acids in the seeds (Krübel et al. 2014). Thus, defects in cysteine degradation probably interfere with protein catabolism in general and might create a shortage of nitrogen supply. However, this option has to be further investigated.

#### *Defects in cysteine catabolism induce metabolic shifts characteristic for developmental senescence*

Plant senescence is a highly coordinated physiological process essential for nutrient remobilization to the growing seeds (Lim et al. 2007). This developmental stage is associated with a shift from anabolic metabolism to catabolic pathways catalyzing the degradation of proteins, carbohydrates, lipids, and nucleic acids in the leaves. Recently, comprehensive metabolite profiles of the senescence process in *Arabidopsis* have been published, providing a catalog of metabolite patterns characteristic for the onset of developmental senescence that can be used as markers (Watanabe et al. 2013). Interestingly, specific shifts in the metabolite profile already occur in presenescent tissues before chlorosis becomes apparent.

We detected several senescence specific metabolite changes in young rosettes of all mutant lines analyzed. The concentrations of amino acids as well as secondary metabolites associated with nitrogen turnover were elevated in the mutants compared to the wild type. High asparagine/aspartate and glutamine/glutamate ratios are typical metabolite markers for the onset of senescence in *Arabidopsis*, and nitrogen-rich amino acids are closely associated with nitrogen remobilization and transport (Watanabe et al. 2013). Polyamines are synthesized from arginine or ornithine and thus interconnected with the major N pools. Due to their high intracellular concentrations they are considered to be major sinks and storage forms of assimilated N and also might play a role in the detoxification of excess ammonium (Moschou et al. 2012). Thus, the increased concentrations of putrescine and spermidine in the mutant plants could be an indication for higher rates of protein turnover. However, in contrast to the nitrogen-rich amino acids high levels of polyamines seem to delay the onset of senescence (Moschou et al. 2012).

A change in the spatiotemporal distribution of TCA cycle intermediates within individual leaves has been shown to occur in *Arabidopsis* plants grown under short day conditions before the onset of senescence (Watanabe et al. 2013). Concentrations of succinate and fumarate were consistently reduced in all three mutants related to cysteine catabolism. Since for the present study samples were harvested at the end of the dark period, the TCA cycle can be assumed to be in the cyclic mode in wild type leaves to meet the high energy demand during the night. Thus, the strong decrease in the central part of the cycle would indicate a change in the flux mode towards production of precursors for other pathways and may be connected to a higher nitrogen turnover (Sweetlove et al. 2010).

Serine and glycine levels have been shown to increase during senescence at least in plants grown under short day conditions (Watanabe et al. 2013). We observed the same trend in young rosettes of the three mutant lines. Glycine and to a lesser extent also serine accumulate during the day due to their role in photorespiration leading to an increased glycine/serine ratio (Timm et al. 2013). High glycine and serine levels in the morning might indicate changes in the photorespiratory pathway that prevent efficient removal at night. In addition, one carbon-metabolism could be affected in the mutants since catabolic reactions of serine as well as glycine transfer methyl groups to tetrahydrofolate (Hildebrandt et al. 2015).

According to these results, defects in the mitochondrial cysteine degradation pathway lead to several metabolic shifts that normally occur during senescence. However, since *str1-1* plants developed normally additional effects were obviously necessary to actually induce premature leaf senescence.

*A persulfide intermediate inhibits amino acid catabolism, affects the C/N status, and induces early senescence under light limitation*

Our results show that the sulfur dioxygenase ETHE1, which is involved in cysteine degradation, is relevant for vegetative growth and the onset of senescence particularly under light limiting conditions. This finding is in line with recent studies demonstrating the important function of autophagy and protein turnover for energy production during the night as well as for nitrogen remobilization (Guiboileau et al. 2012, 2013, Izumi et al. 2013). Autophagy-defective *Arabidopsis* mutants display reduced growth under short-day conditions and earlier and more rapid leaf senescence than the wild type (Guiboileau et al. 2012, Izumi et al. 2013). Thus, regular protein turnover for nutrient remobilization during the night is essential mainly under short light periods. Knockdown ETHE1 could lead to a general disturbance in amino acid catabolism and thus cause similar defects as a block of earlier steps in the autophagic process. Indeed, branched-chain amino acids, aromatic amino acids, and lysine accumulated in young *ethe1-1* plants at the end of the dark period. Energy yield from the oxidation of these amino acids is particularly high, and they typically increase during carbohydrate starvation probably to serve as an alternative substrate for ATP production (Araujo et al. 2011, Hildebrandt et al. 2015). However, we did not detect a depletion of carbohydrates in the *ethe1-1* plants, but in contrast sugar levels except glucose were even increased compared to the wild type. Thus, the accumulation of amino acids was probably not caused by an increase in protein turnover as a reaction to carbohydrate starvation. An alternative explanation could be inhibition or down-regulation of individual steps in the catabolic pathways. Interestingly, the accumulation of amino acids connected to energy metabolism was specific for *ethe1-1* and not present in the *ethe1-1 x str1-1* double mutant indicating that most likely this effect was caused by a persulfide intermediate that is not produced in the absence of the sulfurtransferase. Persulfides are highly reactive (nucleophilic and reducing) and have been identified as critical components of redox cell signaling in mammals (Ida et al. 2014). GSSH as well as protein bound cysteine persulfides are endogenously produced and maintained in animal cells, and our results indicate that these

reactive sulfur species might have a similar function in plant tissues. The catabolic pathways for branched-chain and aromatic amino acids are rather complicated and only partially known in plants (Hildebrandt et al. 2015). Therefore, it is difficult to speculate about which particular step might be inhibited or regulated by a persulfide intermediate, and further, more detailed metabolite analyzes will be necessary to identify the position of the block.

In contrast to the situation in seeds, the function of sulfurtransferase 1 does not seem to be essential for vegetative growth in *Arabidopsis*. The *str1-1* mutant showed no phenotype differences compared to the wild type under the conditions tested indicating that all necessary physiological functions can probably be compensated by one of the additional 19 sulfurtransferase isoforms (Bartels et al. 2007). Most notably, the early senescence phenotype characteristic for *ethe1-1* plants grown under short-day conditions was not present in the Str1 deficient mutant. Thus, like the inhibitory effect on amino acid catabolism premature senescence is most likely caused not by a general decrease in cysteine degradation but rather by accumulation of a persulfide intermediate. In this case it could be expected that the phenotype can be rescued in the double mutant, which we observed only in some of the plants. The high variability in *str1-1* seed development already indicates that the compensation mechanism by sulfurtransferase isoforms does not always work equally well. Therefore, the different phenotypes of the *ethe1-1 x str1-1* double mutant might be due to distinct expression profiles of sulfurtransferases which are able to replace Str1 to a different extent. Considering their potential role in cell signaling the balance between persulfide production and removal can be expected to be critical for plant development, and persulfide accumulation will have different effects depending on the extent, timing and intracellular localization. This interesting aspect has to be further investigated.

Another question still remaining open is which factors actually induce premature senescence under short day conditions in ETHE1 deficient plants. A shift in the C/N-status reflected by an accumulation of hexoses in combination with increased concentrations of amino acids and other metabolites related to nitrogen remobilization is discussed to be an internal signal for the induction of leaf senescence (Aguera et al. 2010, Wingler et al 2009). While metabolites associated with nitrogen remobilization were high in all mutant plants analyzed, hexoses as well as the stress-related sugars galactinol and raffinose particularly accumulated in *ethe1-1* plants. Thus, the increase in free sugar levels in combination with a low nitrogen status might act as a metabolic signal for the onset of senescence in young ETHE1 deficient plants.

However, the mechanistic context between persulfide and sugar accumulation still has to be established.

After 100 days of growth under short day conditions metabolite profiles of wild type and *str1-1* plants clearly indicated that the senescence process had already started although only minor chlorotic patches were visible in the leaves. Some of the characteristic differences detected in *ethe1-1* and *ethe1-1 x str1-1* plants can be attributed to the advanced senescence state of these mutants compared to the wild type (Watanabe et al. 2014). A high degree of chlorosis correlated with increased concentrations of the stress related sugars raffinose and galactinol, as well as the amino acids connected to photorespiration glycine and serine. Levels of ascorbate and dehydroascorbate were low, which might indicate a more oxidized state of the dying cells. In addition, changes in the TCA cycle mode probably reflect the lower energy demand and increased nutrient remobilization during late senescence.

Interestingly, some metabolite patterns detected in *ethe1-1* and double mutant plants were contrary to the characteristic senescence profile of *Arabidopsis* leaves and could therefore reflect specific effects of persulfides. The accumulation of nitrogen-rich amino acids as well as hexoses was clearly reduced in *ethe1-1* plants. Hexose concentrations were also low in the *ethe1-1 x str1-1* double mutant indicating that carbohydrate starvation was induced by the defect in ETHE1 protein and independent of the presence of the sulfurtransferase. Interestingly, nitrogen remobilization correlated with the size of the double mutant plants. Concentrations of arginine, asparagine, and ornithine were low in *ethe1-1* and the small plants of the double mutant but comparable to wild type levels in the big double mutant plants, indicating that growth repression might be connected to consistent changes in the nitrogen status.

## Conclusions

None of the previously published pathways of cysteine catabolism consider the ultimate fate of the thiol group. However, our results clearly demonstrate that a tight regulation of the concentrations of reactive persulfide intermediates is highly important. An exciting question for further research will be whether persulfides also have a defined signaling function in plants as described in animals. By now it is already obvious that either toxic or regulatory effects of persulfides interfere with central aspects of plant metabolism during seed

development as well as vegetative growth under light limiting conditions. Thus, a better understanding of the underlying mechanism will provide a basis for improving plant yield and fitness.

### **Author contributions**

S.H. and M.B. performed and evaluated experiments addressing the individual steps of the cysteine catabolic pathway, C.L. and T.B. characterized the *ethe1-1 x str 1-1* double mutant, T.T. and A.R.F. performed metabolite profiling, H.P.B. contributed to the scientific concept, T.M.H. designed the experiments, evaluated data and wrote the manuscript.

### **Acknowledgements**

We thank Jutta Papenbrock and Pamela von Trzebiatowski (Institute for Botany, Leibniz University Hannover) for providing the plasmid for Str1 expression and valuable assistance during heterologous expression and purification of Str1 and ETHE1. We are also grateful to Antje Bolze (Max-Planck-Institute of Molecular Plant Physiology) for skillful technical assistance during metabolite analysis and Herbert Geyer as well as Jens-Peter Barth (Leibniz University Hannover) for growing the plants.

### Abstract

The sulfur dioxygenase ETHE1 oxidizes persulfides in the mitochondrial matrix and is involved in the degradation of L-cysteine. ETHE1 has an essential but yet undefined function in early embryo development of *Arabidopsis thaliana*. In leaves, ETHE1 is strongly induced by extended darkness and takes part in the use of amino acids as alternative respiratory substrates during carbohydrate starvation. Thus, we tested the effect of darkness on seed development in an ETHE1 deficient mutant compared to the wild type. Since ETHE1 knock out is embryo lethal, the knock down line *ethe1-1* with about 1 % residual sulfur dioxygenase activity was used for this study. We performed phenotype analysis, metabolite profiling and comparative proteomics to investigate the general effect of extended darkness on seed metabolism and further define the particular function of the mitochondrial sulfur dioxygenase ETHE1 in seeds. Shading of the siliques had no morphological effect on embryogenesis in wild type plants. However, the developmental delay that was already visible in *ethe1-1* seeds under control conditions was further enhanced in the darkness. Interestingly, dark conditions strongly affected seed quality parameters of wild type as well as mutant plants. The lipid content of the seeds was severely decreased to about 20 % of light conditions, and there was also a clear reduction in free sugar concentrations. In contrast, amino acids accumulated with the strongest effect on the nitrogen-rich amino acids asparagine and glutamine. Proteome as well as metabolite data revealed a major regulatory effect of light on nitrogen turnover in the developing seeds. In addition, first evidence for a function of branched-chain amino acid catabolism in seed energy production was provided. Knockdown of ETHE1 lead to alterations in endosperm cellularization as well as mitochondrial

structure. Interestingly, the effect on amino acid profiles was clearly different from that found in leaves indicating that in seeds the ETHE1 dependent pathway interacts with alanine and glycine rather than branched-chain amino acid metabolism.

## Introduction

Seed development of plants starts with the unique event of double fertilization. The resulting seed compartments endosperm and embryo undergo specific developmental sequences with dramatic changes on cellular and molecular level from tissue differentiation and growth to storage deposition during seed filling. The endosperm is essential for embryo development. It embeds the embryo and is surrounded by the seed coat. In *A. thaliana* the endosperm is of transient nature and only the aleurone layer remains until seed maturity (Novack et al. 2010). Its development is characterized by a stepwise differentiation including transition from a syncytial to a cellular phase (Olsen 2004, Berger 2003, Brown et al. 2003, Brown et al. 1999). The process of cellularization has a great impact on the accurate embryo development (Hehenberger et al. 2012) and conducts the initiation of embryo growth (Brown et al. 1999). During seed maturation the embryo massively accumulates storage compounds within the cotyledons and becomes a highly specialized storage tissue. At early stages starch and hexoses accumulate transiently, but their amount gradually decreases accompanied by a rapid increase of protein and lipid storage (Borisjuk et al. 2005, Baud et al. 2002). The synthesis of storage compounds requires provision of sufficient amounts of precursor molecules, reductants and energy (Gallardo et al. 2008, Fait et al. 2006). Nutrients such as sugars and amino acids delivered from the mother plant are precursors for storage product biosynthesis in seeds (Melkus et al. 2009). An adaption of energy metabolism including photosynthesis and respiration is essential to enable efficient storage product accumulation. Seed plastids hold special structures and have adapted their metabolism to cope with reduced light levels available for photosynthetic reactions (Borisjuk et al. 2013, Borisjuk et al. 2004). The permeability of gases into seeds is low, and plastidial activity during the maturation phase contributes to oxygen allocation and reassimilation of CO<sub>2</sub> (Borisjuk and Rolletschek 2009, Rolletschek et al. 2005, Borisjuk et al. 2005, Ruuska et al. 2004). Highest photosynthetic activity is observed during storage product synthesis, suggesting a correlation of metabolic processes and photosynthesis (Fait et al. 2006, Ruuska et al. 2002). Recently it was postulated that amino acids are not only precursors for storage proteins within seeds, but might also serve as alternative substrates for mitochondrial metabolism during situations of high energy

demand (Galili et al. 2014). In vegetative tissues amino acid catabolism is induced by carbon starvation situations e.g. periods of extended darkness (Hildebrandt et al. 2015, Araujo et al. 2011 and 2010) First studies denote a potential effect of amino acid degradation also on the energy status of seeds (Credali et al. 2013, Angelovici et al. 2011, Gu et al. 2010, Angelovici et al. 2009, Weigelt et al. 2008, Zhu and Galili 2003). However, biosynthesis as well as catabolism of amino acids in seeds is still largely unknown. The mitochondrial sulfur dioxygenase ETHE1 (AT1G53580) is part of a sulfur catabolic pathway that catalyzes the oxidation of sulfide or persulfides derived from amino acids to thiosulfate and sulfate. In *Arabidopsis* leaves ETHE1 has a key function in amino acid catabolism in situations of carbohydrate starvation such as extended darkness (Krübel et al. 2014). In seeds, ETHE1 knock out leads to alterations in endosperm formation and finally causes seed abortion (Holdorf et al. 2012). It has been shown that a sulfur dioxygenase activity of 1% present in an ETHE1 knock down mutant (*ethe1-1*) is sufficient for embryo survival, but development is severely delayed (Krübel et al. 2014), which underlines the importance of this enzyme for seed metabolism.

This study aimed to investigate the physiological role of the mitochondrial sulfur dioxygenase ETHE1 in seeds. One major aspect was to establish whether the functional context of ETHE1 in leaves, the use of amino acids as alternative respiratory substrates, is relevant during embryo development. Therefore, our experimental approach included shading of the siliques combined with metabolite and proteome analysis. Our results show a strong effect of extended darkness on amino acid metabolism in seeds and indicate an additional role of ETHE1 in cell structure formation.

## Results

A combination of phenotype analysis, metabolite profiling and comparative proteomics was used to investigate amino acid metabolism in general and the particular function of the mitochondrial sulfur dioxygenase ETHE1 in seeds. Since ETHE1 knock out is embryo lethal (Holdorf et al. 2012), the knock down line *ethe1-1* described in Krübel et al. (2014) was used for all experiments.

### **ETHE1 knock down causes a delay in embryogenesis which is further enhanced in the darkness**

In leaves ETHE1 is strongly induced by extended darkness and has a key function in the use of amino acids as alternative respiratory substrates during carbohydrate starvation (Krübel et al. 2014). Thus, we tested the effect of darkness on seed development in the *ethe1-1* mutant by covering the young siliques with aluminium foil one day after pollination (DAP, Supp. Fig. 1). The role of photosynthesis in seeds is still largely unknown. Since carbohydrates are mainly provided by the mother plant, additional functions compared to leaves can be expected. Therefore, we first tested the effect of darkness on seed development in wild type plants. Overall development of the siliques and the number of seeds produced was not influenced by the shading procedure (data not shown). However, the seeds did not turn green at 4-5 DAP like under light conditions but appeared yellowish (Figure 1A). Seeds grown under light and dark conditions were harvested over a period of 1 to 9 DAP. For each time point (1-9 DAP) and light condition (light, dark) embryo development in seeds from 5 siliques was analyzed using a seed clearing method. Interestingly, there were no morphological differences between wild type embryos growing under light or dark conditions. Development from globular to mature stage proceeded very uniformly, and all seeds in a silique were in the same developmental stage (Figure 1B). In contrast, we observed a delay of embryogenesis in *ethe1-1* seeds with several embryo stages present within one silique. Dark conditions induced a stronger phenotype in *ethe1-1* seed, which became apparent starting from 3 DAP were most of the embryos were still in the globular stage, while light grown *ethe1-1* embryos were in the transition stage. At 9 DAP most of the embryos were fully matured, but some were still in the cotyledon and bending cotyledon stage. The

developmental delay of *ethe1-1* seeds compared to the wild type observed under control conditions is further increased by about two days in darkness.

### **Darkness leads to reduced seed weight and a changed biomass composition**

Mature seeds of wild type as well as *ethe1-1* plants grown under light or dark conditions were of the same size and morphologically indistinguishable. However, the final seed weight was drastically reduced in darkness for both genotypes (Figure 2A). To investigate whether the lower weight is caused by a shift in storage product accumulation, we analyzed the final biomass composition of the dormant seeds (Figure 2B). For both, wildtype and *ethe1-1* seeds, lipid contents were decreased to about 20% of light grown seeds. In addition shading of the siliques induced an accumulation of free amino acids. Most notably contents of the nitrogen-rich amino acids Asn and Gln increased more than 20-fold in the darkness compared to control conditions (Figure 2C) In contrast, the protein content was slightly reduced in dark grown seeds, whereas final starch levels remained unaffected. However, concentrations of hexoses and sucrose were strongly decreased after the dark treatment in wild type as well as *ethe1-1* seeds. In agreement with the postulated impact of photosynthesis on germination timing (Allorent et al. 2015), we observed a reduced germination capacity of dark grown seeds (Supp. Fig. 2). Only minor differences were observed regarding biomass composition and germination rate between wildtype and *ethe1-1* seeds.

### **Proteomics and metabolite profiles**

To further investigate the role of ETHE1 in seed metabolism as well as the influence of light on storage product accumulation we performed comparative proteomics and analyzed metabolite profiles of wild type and *ethe1-1* seeds grown under light and dark conditions. Samples were taken at two different time points (Figure 1A, indicated by blue arrows). We selected 5 DAP, since the developmental delay in the mutant seeds was most pronounced at this stage. The endosperm still has an important function and covers a large part of the seed. A second set of samples was collected at 9 DAP, when the seed was completely filled by the embryo and there was no morphological difference between the genotypes or light conditions. Seeds from 8 batches including 10 plants each were pooled and used for shotgun proteomics as well as metabolite

analysis via GC/MS. In total 3958 unique proteins were identified in the shotgun proteomics approach. Technical replicates of the samples clustered very well in a principal component analysis and the different groups were clearly separated so that it was possible to identify sets of differentially abundant proteins (Figure 3). Since the effect of silique shading on the storage compound composition of mature seeds was similar in wild type and *ethe1-1* we first concentrated on the wild type data set to identify the role of light in the seed filling process (Figure 3, comparison 1). We considered 9 DAP to be the most relevant stage for addressing this question because the metabolic activity of the embryo is directed to lipid and storage protein synthesis (Le et al. 2010). Next we analyzed the effect of ETHE1 deficiency on seed metabolism by comparing wild type and mutant seed proteomes at an early (5 DAP) as well as a later (9 DAP) developmental stage (Figure 3, comparison 2a and 2b).

### **Effects of light on seed energy metabolism and storage product accumulation**

The metabolite profiles of wild type as well as *ethe1-1* seeds revealed only a mild shortage of carbohydrates in the absence of photosynthesis. The level of sucrose, which is the main sugar present at 9 DAP, was nearly identical, and also glucose and fructose which are dominant earlier in development were only moderately reduced to 65-95 % of the level present in seeds grown under light conditions. The TCA cycle intermediates citrate, 2-oxoglutarate, succinate, fumarate, and malate were even increased up to 4-fold (Figure 4). In contrast, we detected strong changes in the amino acid composition of seeds grown in shaded siliques (Figure 4). Like already detected in the mature seeds, the most pronounced effect was on amino acids used for nitrogen storage and transport with a 67 fold increase in asparagine concentrations in dark-grown seeds compared to control conditions at 9 DAP. At 5 DAP there was also a clear accumulation of branched-chain and aromatic amino acids detectable in the darkness, which became less pronounced later in development. The proteome comparison indicated a large impact of the availability of light on various metabolic pathways. In wild type seeds harvested at 9 DAP, 338 proteins were of significantly higher abundance in the dark treated samples compared to control conditions and 324 proteins were reduced. To get a global overview of pathways potentially affecting seed composition, proteins were annotated to functional categories, and all spectra obtained from proteins of significantly changed abundance were summed up (Figure 5A). As expected, there was a clear reduction of photosynthesis related proteins including light reaction and Calvin cycle

in dark grown seeds. Interestingly, plastidial proteins with other functions were mainly upregulated. We also detected a strong influence of light on mitochondrial protein composition with several up- and downregulated proteins. A high turnover of lipids was indicated by an increase of proteins related to lipid biosynthesis as well as degradation. Protein synthesis was also increased under dark conditions, while protein degradation as well as amino acid metabolism was rather down regulated. Since metabolite profiling had indicated a strong effect of darkness on asparagine concentrations, we specifically analyzed proteins involved in asparagine metabolism. Aspartate amino transferase 2, which produces aspartate as the precursor for asparagine synthesis, was significantly increased in darkness at 5 and 9 DAP. We also detected 2 peptides of asparagine synthase, but the number of spectra was not sufficient for solid quantification. To identify the most explicit changes induced by darkness, log<sub>2</sub> ratios of differentially abundant proteins were plotted to the number of spectral counts. By considering a fold change of at least 1.5 and a minimum of 5 spectral counts to represent major changes, the number of regulated proteins decreased to 76 proteins with higher abundance and 99 proteins with lower abundance in dark grown seeds of wildtype compared to light conditions (Figure 5B). As expected, the majority of proteins with a decreased abundance in darkness are related to light reactions of photosynthesis such as photosystem I and II and cytochrome b6f subunits. In addition, dark grown seeds show a reduced abundance of proteins balancing redox levels such as stromal ascorbate peroxidase, glutathione-disulfide reductase, copper/zinc superoxide dismutase 1, peroxiredoxin-2E and thioredoxin 3, whereas proteins related to fatty acid degradation (transducin family protein, cycloartenol synthase 1) and proteins involved in nucleotide metabolism (pyrimidine 1, purine biosynthesis 4, Inosine-5'-monophosphate dehydrogenase 2, carbamoyl phosphate synthetase B) showed an increased abundance. Several enzymes related to protein turnover and fatty acid synthesis were strongly affected by changing light conditions. However, proteins annotated to these pathways showed a regulation in both directions suggesting that instead of regulating a whole pathway, individual sub-steps are modulated.

### **Effects of ETHE1 deficiency on seed metabolism and development**

While the composition of mature seeds was very similar in the ETHE1 knockdown mutant and in the wild type, specific differences in the metabolite profile became apparent at earlier developmental stages (Figure 4). At 5 DAP alanine and glycine concentrations were 4 to 5 fold

increased compared to the wild type under light as well as dark growth conditions. Comparison to the metabolite profile of wild type seeds harvested at 4 DAP confirmed, that this effect was not due to the earlier developmental stage present in the mutant. There was a trend towards a general increase in free amino acids in *ethe1-1* seeds compared to the wild type (on average 1.7 fold in the light and 1.9 fold in the darkness) (Figure 4C). Hexose levels in the mutant were also elevated at 5 DAP, which could however be linked to the earlier developmental stage of the *ethe1-1* embryo, since in the wild type hexose concentrations decreased between 4 and 5 DAP (Figure 4A). Sucrose as well as TCA cycle intermediates were unaffected (Figure 4C). At 9 DAP the metabolite profiles of the ETHE1 deficient seeds were more similar to the wild type than at the earlier stage. Amino acid concentrations were only slightly increased (on average 1.3 fold), hexose levels were 1.5-2.5 fold higher, and sucrose was decreased to 70 % of wild type level in the light and to 60 % in shaded siliques.

The proteome analyses of *ethe1-1* seeds compared to wildtype revealed 175 (5 DAP) and 291 (9 DAP) proteins significantly higher in abundance whereas 176 (5 DAP) and 199 (9 DAP) proteins showed a reduced abundance (a full list of proteins with significantly changed abundance is given in the supplementary material). To get a global overview of pathways potentially influenced by ETHE1, proteins were annotated to functional categories and all spectra obtained from proteins of significantly changed abundance at 5 DAP and 9 DAP were summed up (Figure 6A, Figure 7A). To characterize the proteome changes induced by an ETHE1 knock down in more detail, log 2 ratios of differentially abundant proteins observed at 5 DAP and 9 DAP were plotted to the number of spectral counts. A fold change of at least 1.5 and a minimum of 5 spectral counts were considered representing major changes (Figure 6B, Figure 7B).

Overall, the proteome profiles of *ethe1-1* seeds show similar patterns of regulated pathways at the two stages investigated, mainly affecting mitochondrial metabolism, protein turnover, amino acid metabolism and cell organisation. However, the *ethe1-1* seed proteome at 9 DAP differs from that at 5 DAP in respect to light reaction of photosynthesis, Calvin cycle and other plastidial proteins, which are decreased at 5 DAP and increased at 9 DAP compared to wildtype proteomes. Proteins related to sucrose metabolism such as sucrose synthase 1 and sucrose phosphate synthase 1F are exclusively increased in *ethe1-1* seeds at 5 DAP. Protein turnover might be enhanced in *ethe1-1* seeds during development indicated by increased abundance of proteins

related to protein biosynthesis as well as degradation at both stages. In contrast proteins related to amino acid metabolism are reduced at 5 DAP (tryptophan synthase beta-subunit 1, acetylornithine aminotransferase) and 9 DAP (glutamate synthase 2, glutamine synthase, S-adenosyl-l-homocysteine hydrolase 2, dehydroquinase dehydratase, alanine:glyoxylate aminotransferase 3, aspartate aminotransferase 3 and cysteine synthase C1). However, although alanine concentrations were strongly increased in the mutant seeds at 5 DAP, there was no significant effect on protein abundance of alanine aminotransferase 1 catalyzing synthesis as well as degradation of alanine (1.16 fold at 5 DAP, 1.19 fold at 9 DAP). Several enzymes involved in cell wall formation were significantly changed in abundance at 5 DAP (UDP-arabinopyranose mutase 1, root hair defective 3 GTP-binding protein, beta-1,3-glucanase 3, beta glucosidase 18 and PHE ammonia lyase 1) and 9 DAP (FASCICLIN-like arabinogalactan protein 8, beta-D-xylosidase 4, pectinacetyltransferase family protein, UDP-D-apiose/UDP-D-xylose synthase 2). In addition *ethe1-1* seeds show an accumulation of tubulin at 5 DAP which is further increased at 9 DAP.

#### *ETHE1 knock down leads to impaired endosperm cellularization*

Endosperm cellularization has been shown to be affected by ETHE1 knockout (Holdorf et al. 2012), and our proteomic results indicate that changes in cell wall establishment and cellular organization are also present in the knockdown line *ethe1-1* at 5 DAP as well as 9 DAP. Therefore, we measured the size of central endosperm cells obtained at 7 DAP, in microscopic sections of wild type as well as mutant seeds stained with Toluidine Blue O (Figure 8A and B). The area of about 50 cells per sample type was calculated. The average cell size in wild type endosperm was  $156 \pm 40 \mu\text{m}^2$ . In contrast *ethe1-1* seeds showed characteristically enlarged endosperm cells with a size of  $305 \pm 96 \mu\text{m}^2$ . Darkness further increased the endosperm cell size in the mutant, while endosperm of wildtype seeds was not affected.

#### *Aberrant mitochondria in ethe1-1 seeds*

Previous results obtained with the ETHE1 knockout mutant (Holdorf et al. 2012) as well as our proteome study indicate potential effects of ETHE1 deficiency on seed mitochondria. Therefore, we next investigated the ultracellular structure of embryo and endosperm cells in *ethe1-1* at

5 DAP by using transmission electron microscopy (TEM). The overall organellar structure was relatively normal compared to wildtype, with the exception of the appearance of mitochondria (Figure 8C). The main population of mitochondria in both wildtype and *ethe1-1* were similar in structure (e.g. well distinguished double membrane, lamellar cristae, and relative small area of electron-transparent matrix). The maximal differences in size of mitochondria in embryo of wildtype cells (0.08-0.28  $\mu\text{m}^2$ ) and of *ethe1-1* (0.04-0.38  $\mu\text{m}^2$ ) displayed high heterogeneity of population in both genotypes. Similar results were achieved by comparison of mitochondria in endosperm, namely mitochondria size in wildtype (0.05-0.42  $\mu\text{m}^2$ ) and *ethe1-1* (0.04-0.34  $\mu\text{m}^2$ ). Extremely high variability of individual organelles did not allow defining any statistically significant differences. However, embryo cells of *ethe1-1* showed aberrant mitochondria, which differed from wildtype at the ultrastructural level in means of strongly enlarged size (up to 5-fold in length), less pronounced lamellar cristae, larger electron transparent areas in the matrix and some electron-dense insertions (Figure 8C).

## Discussion

The sulfurdioxygenase ETHE1, which is involved in cysteine catabolism, has an essential but yet undefined function in *Arabidopsis* seed development. In this study, metabolomics and shotgun mass spectrometry based proteomics were implemented to (i) investigate the general role of amino acid metabolism in seeds and the specific impact of changing light conditions on seed filling and (ii) the characterization of ETHE1 function in developing seeds.

### Impact of changing light conditions on seed metabolism

#### *Darkness reduces the seed filling capacity*

In several dicotyledonous species such as *Arabidopsis* embryos become green during development. Seed plastids differ in their structure from those present in leaves, and since carbohydrates are mainly supplied by the mother plant, one can assume that plastidial metabolism is changed as well (Ruuska et al. 2002). Nevertheless, it has been proposed that seed photosynthesis has a great impact on seed metabolism and supports efficient storage product accumulation (Andriotis et al. 2010, Fait et al. 2006, Goffman et al. 2005). Our results confirm

that shading of siliques, which obviously prevents photosynthesis, has a great impact on storage metabolism characterized by reduced lipid and sugar levels, slightly reduced protein content and an accumulation of free amino acids in the seeds. It is very likely that the reduced storage capacity in darkness leads to the lower seed weight we observed, since under light conditions storage product accumulation coincides with increasing seed weight (Baud and Lepiniec 2009). Similar results were obtained in a previous study on *B. napus* seeds grown in darkness (Borisjuk et al. 2013). Since gas diffusion into seeds is low, a major function of seed photosynthesis in fatty acid synthesis might be to supply oxygen required for mitochondrial ATP production (Borisjuk and Rolletschek 2009, Borisjuk et al. 2005). Interestingly, we found an accumulation of TCA cycle intermediates in dark grown seeds, which could be an indication for decreased respiration rates. The role of photosynthesis in seed development can also be studied by using inhibitors (Allorent et al. 2015). Brushing of *Arabidopsis* siliques with DCMU to block photosystem II activity had no effect on storage protein or lipid content. Also, only minor differences in primary metabolites were detected, with the exception of an increase in GABA, proline and galactinol. Therefore, it can be assumed that darkness applied to the growing seeds might cause additional effects on development and metabolism.

#### *Darkness induces an accumulation of nitrogen-rich amino acids*

Nitrogen loading of the seeds is achieved via the import of amino acids (asparagine, glutamine, and alanine), which during seed filling are mainly used for storage protein synthesis (Higashi et al. 2006). We observed that the nitrogen-rich amino acids asparagine (Asn) and glutamine (Gln) were most dramatically increased under dark conditions. One reason for this effect could be an induction of Asn synthesis in the absence of light. In leaves asparagine synthetase shows a diurnal pattern of activity and is inhibited by light as well as high levels of reduced carbon (Nozawa et al. 1999). So far no information is available on the relevance of Asn synthesis vs. import in seeds, but it is postulated that Asn has a role in storage product accumulation and might act as signal of the internal nitrogen status (Hernandez-Sebastia et al. 2005). We detected asparagine synthase in our seed proteome data set, but the number of detected spectra was too low for quantification. Another reason for the accumulation of Asn during darkness might be reduced nitrogen uptake by the embryo. It is known that nitrogen uptake of the embryo is realized by amino acid permease 1 (AAP1), and a defect of this transporter results in accumulation of

amino acids in the endosperm at early developmental stages due to limited amino acid shuffling to the embryo (Sanders et al. 2009). Asn is imported from the mother plant and subsequent degradation and metabolism might be important to produce other essential amino acids. It has been shown that defective Asn catabolism causes abnormal seeds and reduced seed weight in *L. japonicus* (Credali et al. 2013). However, we were not able to identify asparaginase in our seed samples.

*Darkness induces accumulation of branched chain and aromatic amino acids at early stage of seed development*

In vegetative tissues, amino acids serve as alternative substrate for mitochondrial respiration in situations of carbon starvation induced by extended darkness (Araujo et al. 2011). The branched-chain amino acids valine, leucine, and isoleucine as well as lysine are particularly relevant in this functional context since their catabolic pathways produce high amounts of ATP and directly transfer electrons into the respiratory chain. Today only limited information on amino acid metabolism in seeds is available. Recently, results related to amino acid catabolism obtained from leaves were hypothetically transferred to seeds. It is proposed that in response to specific developmental processes and stress situations, amino acid catabolism together with photosynthesis contributes to energy supply in seeds (Galili et al. 2014). The metabolite profiles of dark grown seeds revealed only a mild shortage of carbohydrates in the absence of photosynthesis, which was expected since sugars are delivered from the mother plant and further metabolized (Melkus et al. 2009). Thus, shading of the silique does not necessarily induce carbon starvation conditions, but we could show that it nevertheless induces amino acid accumulation. Interestingly, at least in young seeds (at 5 DAP) levels of branched-chain and aromatic amino acids were clearly elevated. This first experimental evidence highlights that amino acids are presumably not only used for protein biosynthesis but might also contribute to the energy status in developing seeds by alternative respiration.

## Physiological function of ETHE1 in seeds

### *ETHE1 is required for cell organisation and cell wall establishment*

Phenotype analysis revealed that *ethe1-1* mutants display a higher sensitivity to changing light conditions, indicated by an enhanced delay of embryogenesis during darkness. However, the final biomass composition of the dormant seeds was not affected by a knock down of ETHE1. In *ethe1-1* seeds, the endosperm is composed of enlarged irregularly shaped cells during cellularization. Our proteomic results confirm that ETHE1 is involved in the establishment of cell walls during development. Proteins related to cell wall degradation such as glucanase and glucosidase were increased in abundance in the mutant compared to the wild type and cell wall proteins were reduced. Overall, we found high amounts of tubulin in *ethe1-1* seeds. In plants, tubulins accumulate during high activity of cell division, cell expansion processes, and also during development (Wasteneys 2002). A high turnover of cell wall elements and defective cell structure establishment might not only affect endosperm cellularization but also nutrient transport to the embryo during development of *ethe1-1* seeds. It has been shown that a mutant blocking transfer cell formation (pea E2748) is defective in normal establishment of embryonic epidermis, which induces enlarged cell wall layers and impaired embryo growth (Borisjuk et al. 2002). Therefore, proper tissue formation is essential for nutrient transport. Our data might indicate that *ethe1-1* mutant embryos suffer from nutrient starvation due to impaired tissue formation. It is proposed that a switch from high hexose to high sucrose level is essential to ensure proper differentiation and cell expansion that elevates storage activity of the embryo (Rolland et al. 2006, Weber et al. 2005). At 5 DAP high concentrations of glucose and fructose and comparatively low levels of sucrose were detected. Enhanced abundance of sucrose synthase activity might induce an increase of relative levels of hexoses observed in *ethe1-1* seeds. However, analyzing wildtype seeds with an equal embryo stage (4 DAP) indicates that the difference observed are rather linked to the general delay of seed development than to a specific ETHE1 function. The switch to high sucrose levels required for proper embryo development is clearly visible at 9 DAP, though sucrose levels are decreased in *ethe1-1* compared to wildtype seeds.

*ETHE1 knock down leads to accumulation of amino acids and impaired mitochondrial structure*

Amino acid concentrations in *ethe1-1* seeds show a general trend towards accumulation compared to the wildtype. In particular, *ethe1-1* seeds accumulated high amounts of alanine and glycine. The endosperm is the first sink within the seed, and amino acids concentration is high during early stages. [Melkus et al. \(2009\)](#) demonstrated that a decrease of amino acid levels in the endosperm coincides with storage activity in the embryo. At 5 DAP the abundance of photosynthesis related proteins was reduced in *ethe1-1* seeds. Therefore oxygen supply at that time can be expected to be rather low and might facilitate anoxic conditions. Evidence is given that alanine accumulates under hypoxic conditions ([van Dongen et al. 2013](#)) and it is proposed that the catalytic activity of alanine aminotransferase is involved in low-oxygen tolerance due to degradation of alanine after hypoxia ([Miyashita et al. 2007](#)). Indeed, protein abundance of alanine aminotransferase was slightly, albeit not significant, increased in the mutant (1.16 fold at 5 DAP and 1.19 fold at 9 DAP). Another line of evidence is given by the presence of unusually shaped, enlarged mitochondria in *ethe1-1* seeds. Recently it has been shown that in leaves the establishment of giant mitochondria is induced by darkness, at reduced carbon levels and under hypoxia ([Jaipargas et al. 2015](#)). However, for seeds only little information on mitochondrial structure is available. Giant mitochondria were observed in the egg cells during double fertilization, but so far not in other stages of embryogenesis ([Kuroiwa and Kuroiwa 1992](#)). *ETHE1* knock down leads to a severe defect in mitochondrial structure, underlining its importance in seed energy metabolism.

## Material and Methods

### *Plant growth and seed harvesting*

*A. thaliana* wildtype (ecotype Columbia) and *ethe1-1* (SALK\_021573, Nottingham Arabidopsis Stock Centre, University of Nottingham) plants were grown in a climate chamber under longday conditions (16h light/8h dark, 22°C, 85  $\mu\text{mol s}^{-1} \text{m}^{-2}$  light intensity and 65% humidity). Flowers were labeled at the day of pollination. Subsequently siliques were harvested from 1 to 9 DAP. For dark treatment, siliques were shaded with aluminium foil 24 hours after flower tagging while the rest of the plant and control siliques were grown under normal light conditions.

### *Phenotypic analysis of seed samples*

Whole-mount preparations were used for microscopic analysis of *A. thaliana* wildtype and *ethe1-1* embryo development grown under light and dark conditions. Seeds from at least 5 siliques each were cleared by incubation with Hoyer's solution [15 mL distilled water, 3.75 g gum Arabic, 2.5 mL glycerine, 50 g chloral hydrate] overnight. Embryo development was analysed by using a Normarski optics and light microscopy. Observed embryo stages were counted. For analyzing seed tissue differentiation histological sections were prepared from 7 DAP *ethe1-1* and wildtype seeds grown under light and dark conditions. Seed samples were fixed with 1.25% formaldehyde and 0.1 M phosphate buffer overnight followed by dehydration of the samples by a series of ethanol aqueous solutions (30-99%). After dehydration samples were infiltrated with HistoResin (Leica). Sections of 3.5  $\mu\text{m}$  were prepared using a microtome (HYRAX M55, Zeiss) and Sec55 low profile blades (MICROM). Sections were stained with 0.5% Toluidine Blue O in 200mM phosphate buffer. Photographs of cleared seeds and sections were taken with a Zeiss microscope (Axioskop2) and AxioCam MRc5 camera. Seed size and weight were measured for dormant seeds of *ethe1-1* and wildtype grown under light and dark conditions for 100 seeds each. Significant differences were calculated using a Student's t-test (p-value  $\leq 0.05$ ). For electron microscopy of mitochondria seeds of wildtype and *ethe1-1* (5 DAP) were fixed and embedded in accordance to [Tschiersch et al. \(2011\)](#). Digital records of seed mitochondria were made on a Zeiss 902 electron microscope at 80 kV.

### *Germination rates*

*Arabidopsis* seeds of wildtype (ecotype Columbia, Col0) and *ethe1-1* grown under light and dark conditions were surface sterilized with 6% sodium hypochloride and 100% ethanol followed by five washing steps with sterilized water. For vernalization seeds were incubated for 2 days at 4°C in the dark. Approximately 20 seeds were sown per plate (3 replicates per sample) on MS-medium [60mM sucrose, 1% Agar, 0.5% MS-medium (Duchefa), pH 5.7-5.8 with KOH] and MS medium without a carbon source and incubated for another 2 days at 4°C in the dark. Afterwards the plates were placed to a growth chamber (24°C, 16 h light/8 h dark). After 72h germinated seeds were counted. A seed is considered to be germinated when the radicle ruptures the endosperm and the testa.

### *Silique culture*

Siliques were harvested from wildtype and *ethe1-1* plants at 2 DAP and cultured in a medium [1.5% MS and 2mM MES, pH 5.6] (control). For amino acid treatments 0.1mM, 0.5mM and 1 mM cysteine and leucine were added to the silique culture. A concentration of 10 mM resulted in seed abortion for both genotypes (data not shown). Siliques were cultured for 3 days in a climate chamber under longday conditions (seed stage equivalent to 5 DAP). Subsequently, seeds were harvested and embryo stages investigated by seed clearing and light microscopy as described above.

### *Metabolite profiling*

Metabolites of *ethe1-1* and wildtype seeds (4, 5 and 9 DAP) grown under light and dark conditions were extracted and subsequently analysed by GC-TOF MS as described by [Lisec et al. \(2006\)](#). Chromatograms and mass spectra were evaluated by using TagFinder 4.0 software ([Luedemann et al., 2008](#)) and Xcalibur 2.1 software (Thermo Fisher Scientific, Waltham, USA). Metabolites were identified in comparison to database entries of authentic standards ([Kopka et al., 2005](#); [Schauer et al., 2005](#)). Peak areas of the mass (m/z) fragments were normalized to the internal standard (ribitol) and fresh weight of the seed samples. Identification and annotation of detected peaks followed recent recommendations for reporting metabolite data ([Fernie et al.,](#)

2011). Metabolites (starch, total proteins, total lipids and amino acids) of dormant wildtype and *ethe1-1* seeds grown under light and dark conditions were extracted and analyzed as described in Schwender et al. (2015).

#### *Sample preparation for mass spectrometry*

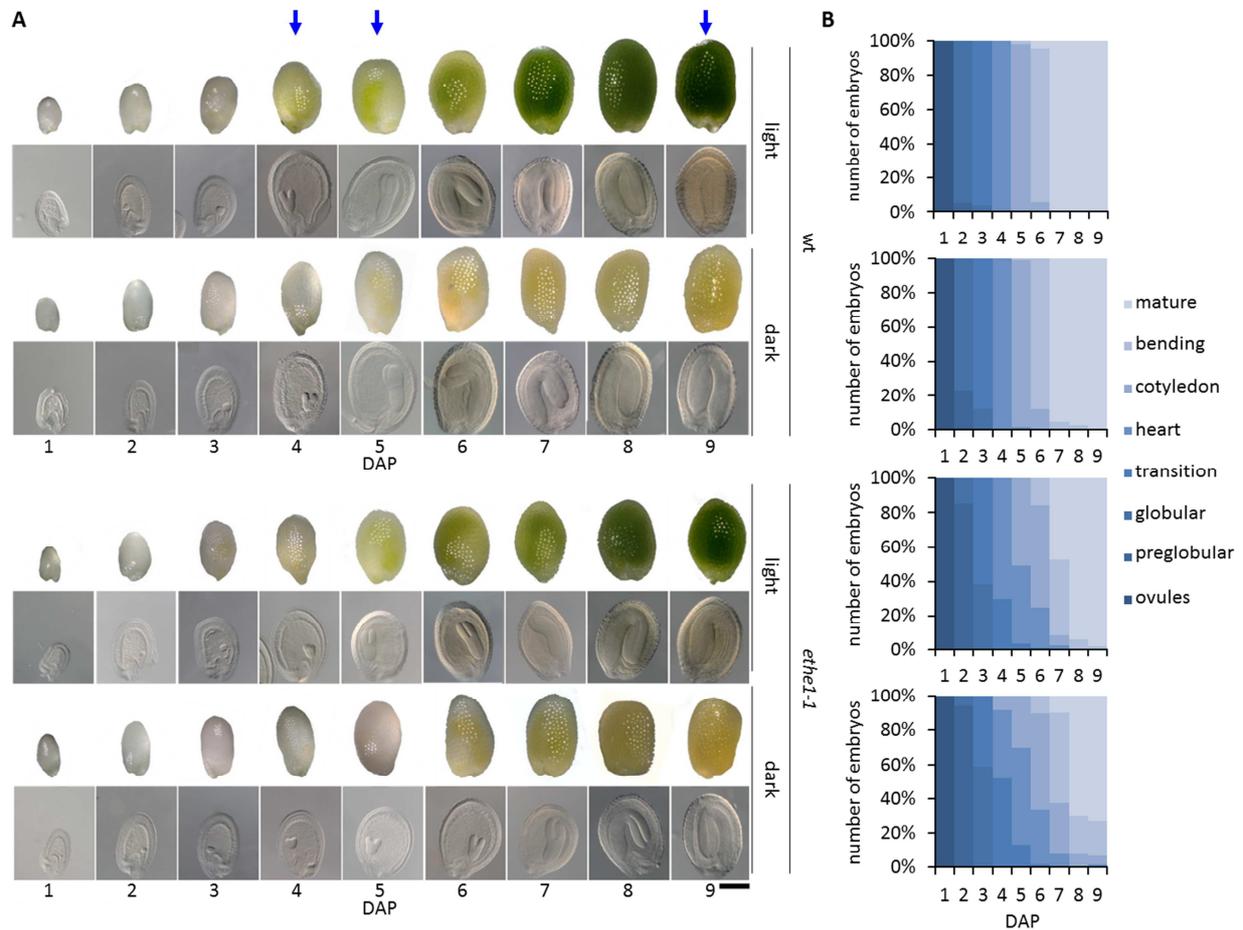

Proteins of wildtype and *ethe1-1* (5DAP, 9 DAP, light, dark) were extracted from 30 mg of pulverized seeds (pooled sample) by adding 150  $\mu$ L extraction buffer [4% SDS (w/v), 125mM TRIS, 20% glycerol (v/v)] and incubating at 60°C for 5 min. Another 150  $\mu$ L of ddH<sub>2</sub>O were added to the sample followed by centrifugation at 18000xg for 10 min. The protein concentration of the supernatant was measured by using the Pierce™ BCA Protein Assay Kit (Thermo Fisher Scientific, Dreieich, Germany). To each sample (total protein 50  $\mu$ g) 2-mercapto ethanol with a trace of bromophenol blue was added to a final concentration of 5%. SDS gel electrophoresis using a 1D glycine gel (stacking gel 4% acrylamide, separating gel 14% acrylamide) was performed according to Leammli (1970). The gel run was stopped before proteins entered the separation gel. The gel was fixed with 10% (v/v) acetate in 40% (v/v) methanol for 45 min and stained with Coomassie blue CBB G-250 (Merck, Darmstadt, Germany) for 30 min as described by Neuhoff et al. (1985 and 1990). Gel bands were cut using a scalpell and diced into 1.0-1.5 mm cubes. Carbamidomethylated followed by tryptic digestion and extraction of proteins was performed according to Klodmann et al. (2010). Resulting peptides were resolved in 20  $\mu$ L of 2% [v/v] ACN, 0.1% [v/v] formic acid (FA) prior to MS analysis.

#### *Shot gun mass spectrometry and relative protein quantification*

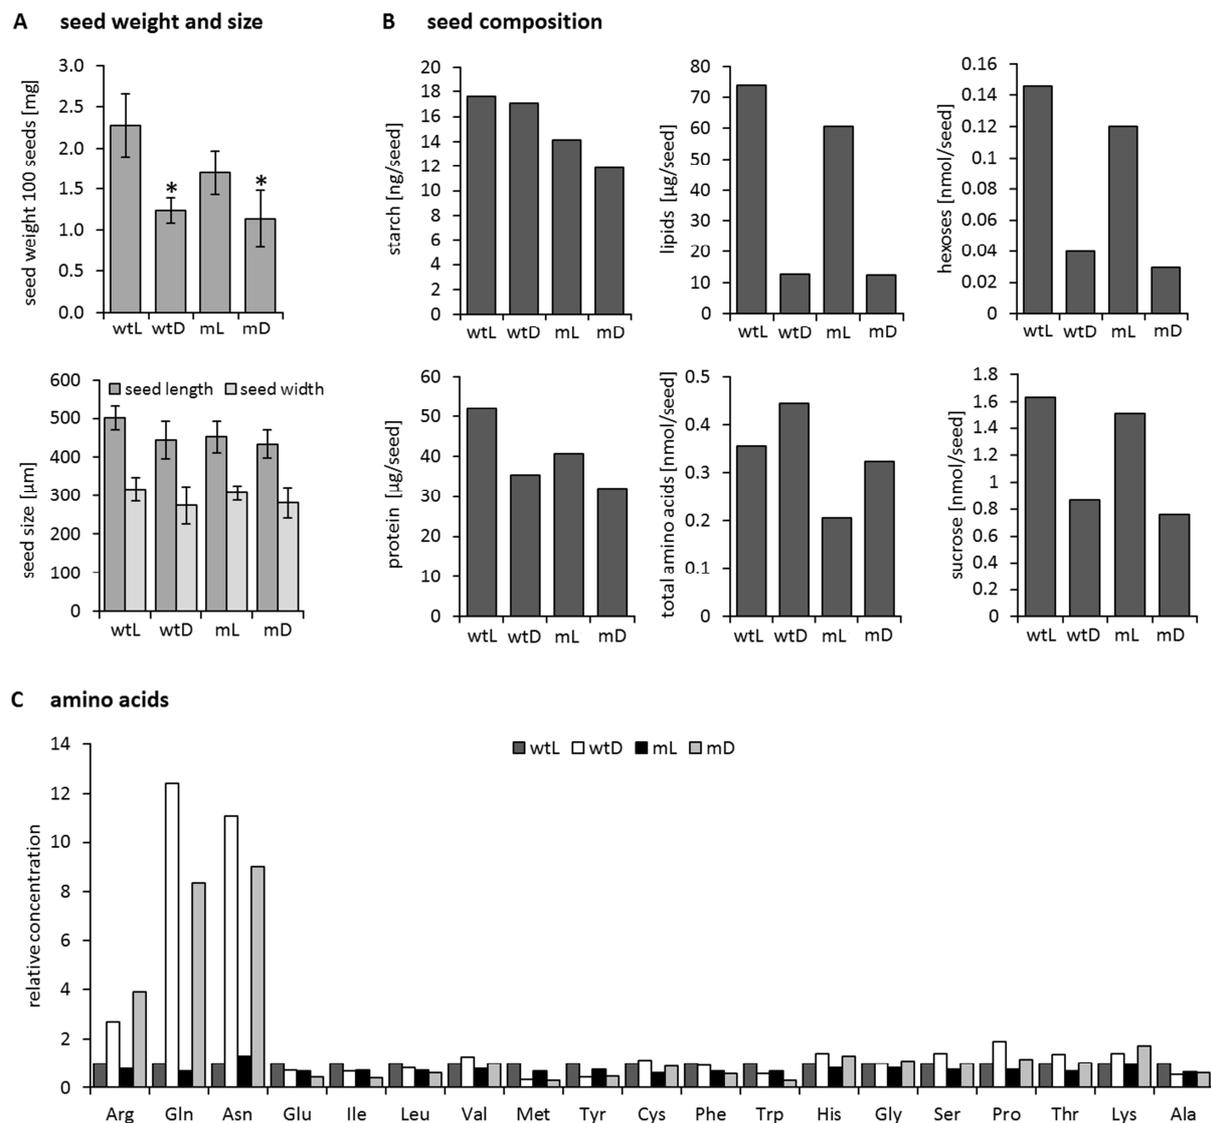

Shot gun mass spectrometry was performed by using a Q-Exactive (Thermo Fisher Scientific, Dreieich, Germany) mass spectrometer coupled to an Ultimate 3000 (Thermo Fisher Scientific, Dreieich, Germany) UPLC. Three times (technical replicates) four microliter of peptide solution per seed sample were injected into a 2 cm, C18, 5  $\mu$ m, 100 Å reverse phase trapping column (Acclaim PepMap100, Thermo Fisher Scientific, Dreieich, Germany). Peptide separation was done on a 50 cm, C18, 3  $\mu$ m, 100 Å reverse phase analytical column (Acclaim PepMap100, Thermo Fisher Scientific, Dreieich, Germany). Peptides were eluted by using a non-linear 2% [v/v] to 34% [v/v] acetonitrile gradient in 0.1% [v/v] formic acid of 60 minutes. For MS analysis

a spray voltage of 2.2 kV, capillary temperature to 275°C and S-lens RF level to 50% was tuned. For full MS scans, the number of microscans was adjusted to 1, resolution to 70,000, AGC target to 1e6, maximum injection time to 400 ms, number of scan ranges to 1 and scan range to 400 to 1600m/z. For dd-MS2, the number of microscans was adjusted to 1, resolution to 17,500, AGC target to 1e5, maximum injection time to 120 ms, Loop count to 10, MSX count to 1, isolation window to 3.0 m/z, fixed first mass to 100.0 m/z and NCE to 27.0. Data dependent (dd) settings were adjusted to underfill ratio of 0.5%, intensity threshold to 2.0e3; apex trigger to 10 to 60 s, charge exclusion to unassigned 1, 5, 5 – 8, >8, peptide match to preferred, exclude isotopes to on and dynamic exclusion to 45.0 s. Protein identification and was done by using Proteome Discoverer (Thermo Fisher Scientific). MS/MS data were queried against the Tair10plus database using the MASCOT search engine (peptide confidence high, minimum peptide count 1). For quality control of MS shotgun run a principle component analysis (PCA) using Perseus software was performed. Protein abundance was quantified by spectral counting and significant differences between samples were calculated using a Student's t-test ( $p\text{-value} \leq 0.05$ ).

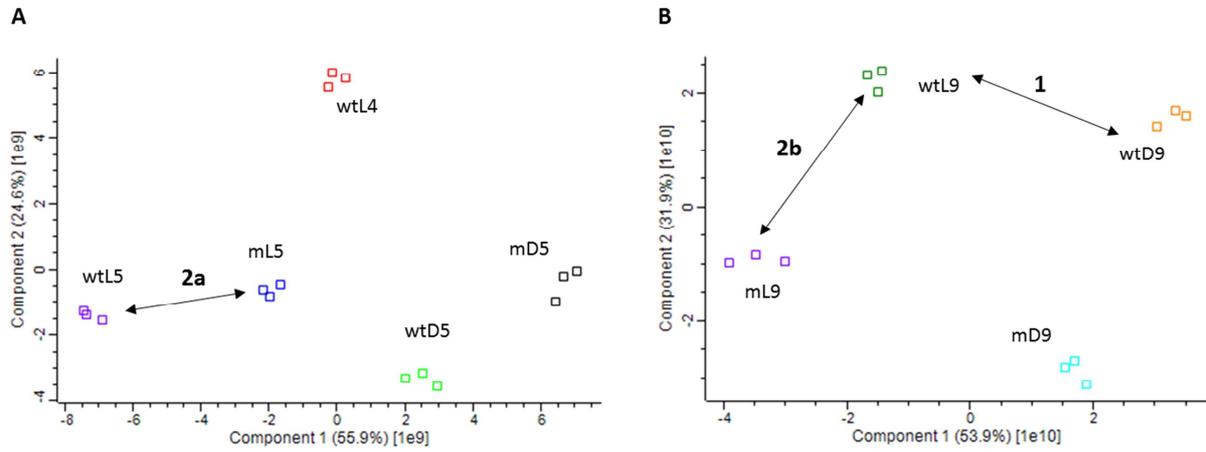

## Figures

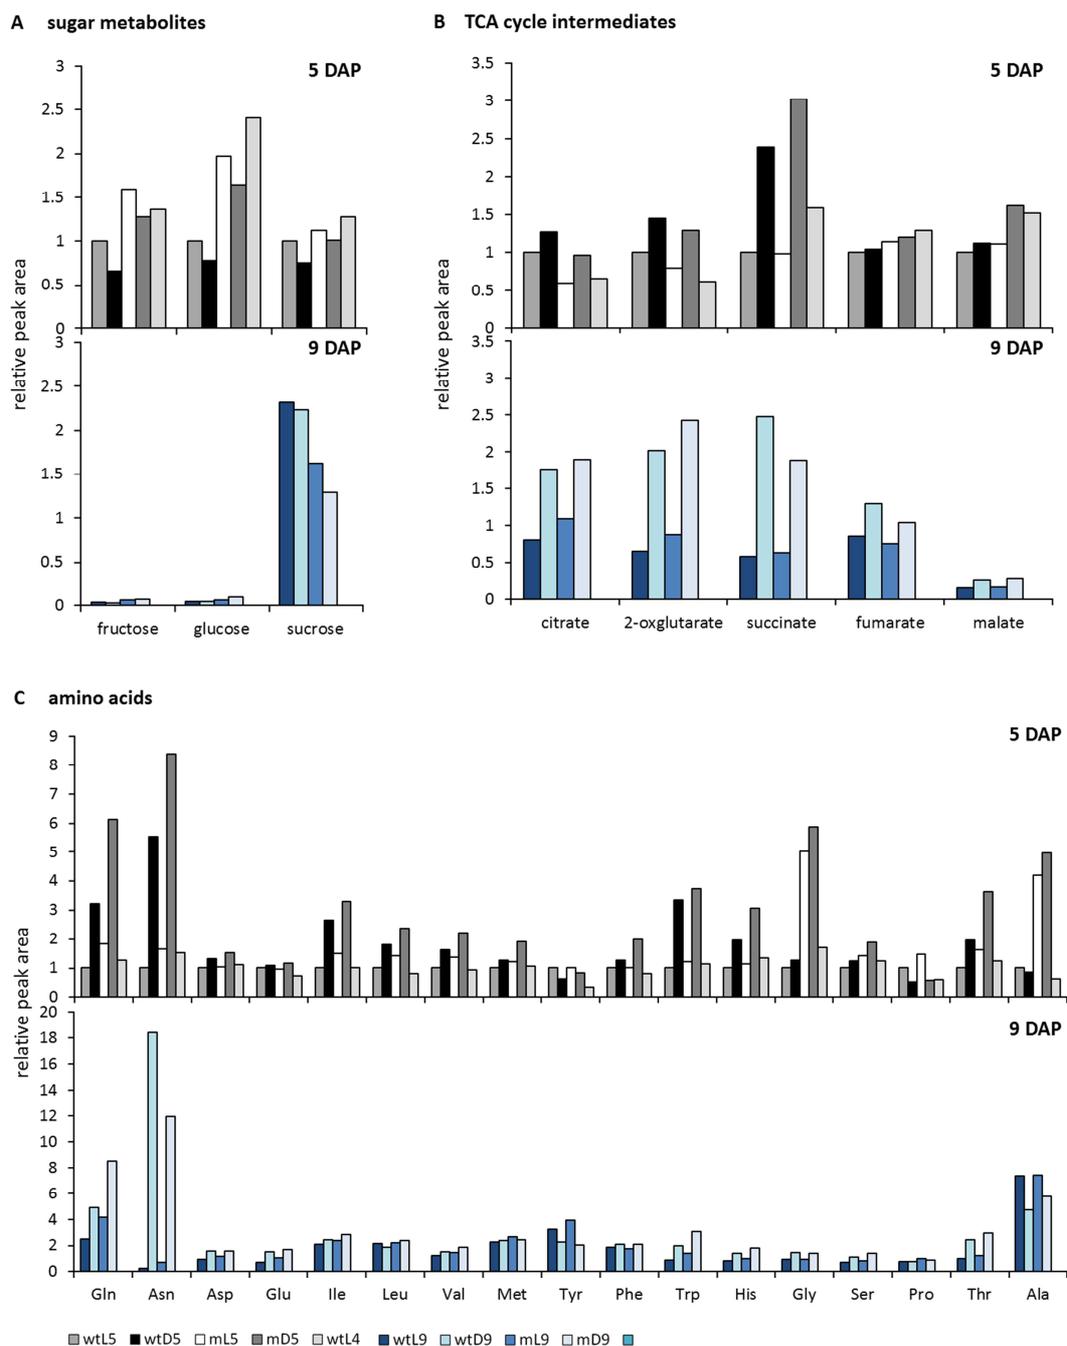

**Figure 1: Seed development of *A. thaliana* wildtype and *ethe1-1* seeds under light and dark conditions. A:** Representative seeds and embryos of wildtype (wt) and *ethe1-1* from 1 to 9 days after pollination (DAP) grown under light and dark conditions, bars = 100  $\mu$ m. **B:** Progression of embryo development in wt and *ethe1-1* seeds. A total of 180 siliques and 7781 seeds between 1 and 9 DAP were analyzed of wildtype and *ethe1-1* grown under light and dark conditions. Blue arrows indicates stages investigated by metabolomics and proteomics.

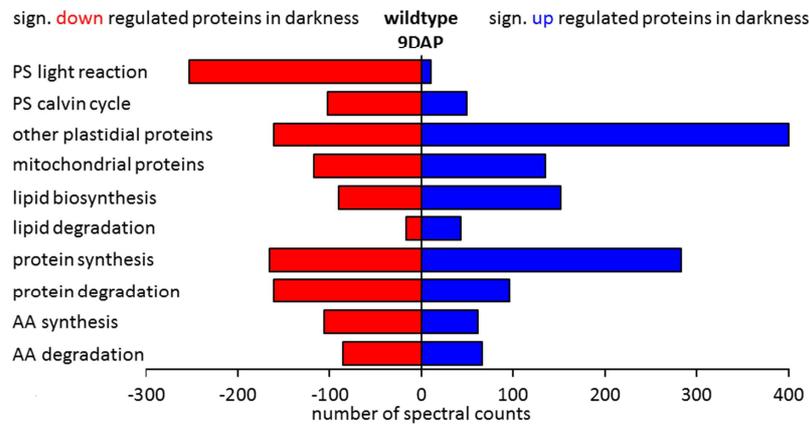

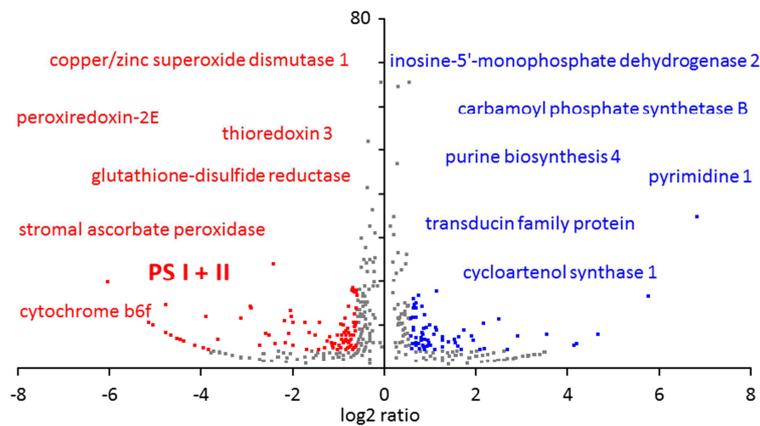

**Figure 2: Seed weight, seed size and biomass composition of dormant seeds.** **A:** Seed size and weight of 100 dormant seeds from wildtype and *ethe1-1* plants grown under light and dark conditions. Asterisks indicate significant changes based on a Student's t-test ( $p\text{-value} \leq 0.05$ ) **B:** Storage compounds and amino acids were extracted from dormant seeds from wildtype and *ethe1-1* grown under light and dark conditions and quantified. **C:** amino acid profiles of dormant seeds from wildtype and *ethe1-1*. **wtL** wildtype seeds grown under light conditions, **wtD** wildtype seeds grown under conditions dark conditions, **mL** *ethe1-1* seeds grown under light conditions, **mD** *ethe1-1* seeds grown under dark conditions.

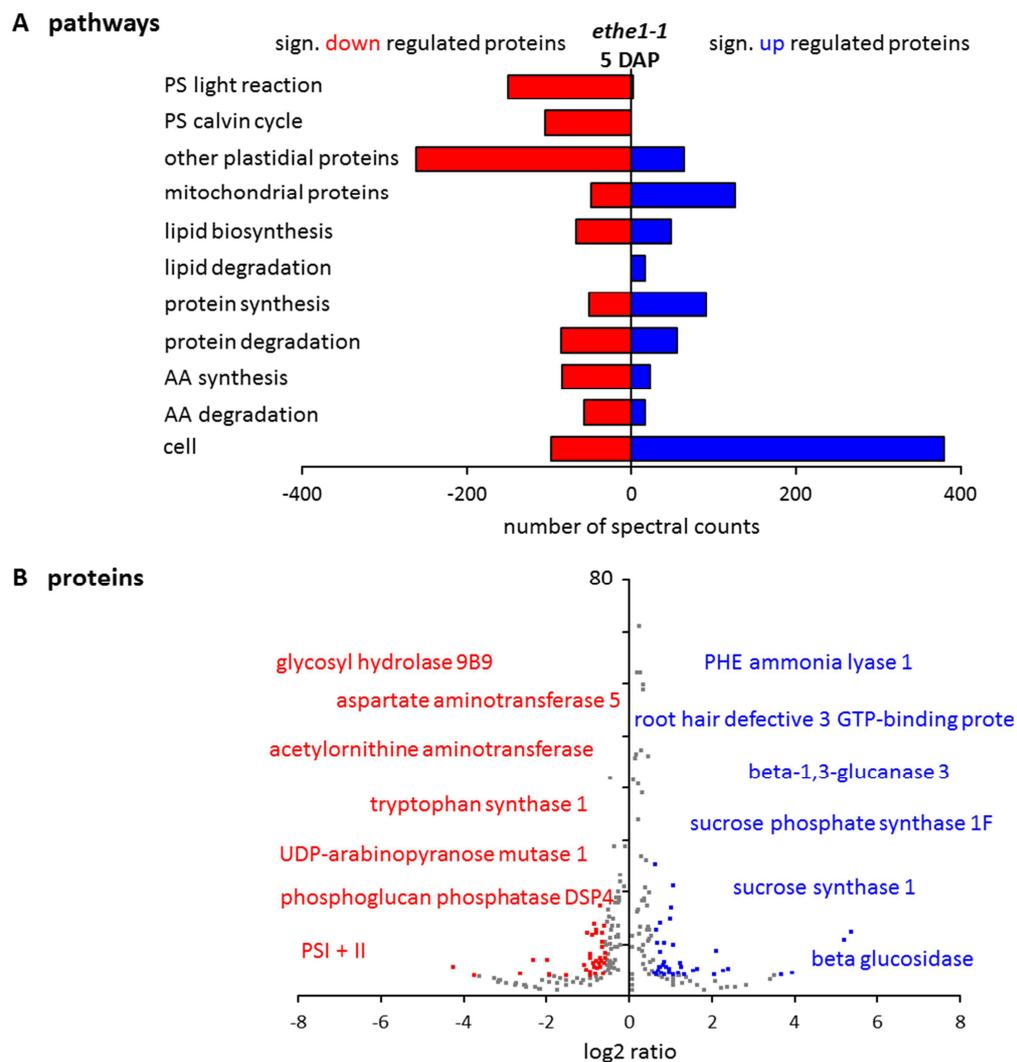

**Figure 3: Principle component analysis and overview of proteomic comparisons.** For quality of shotgun mass spectrometry data principle component analysis (PCA) was performed by using Perseus software. Proteomic comparisons are indicated by numbers (**1**, **2a**, **2b**) in the PCA plots of 4 and 5 DAP seeds (**A**) and 9 DAP seeds (**B**).

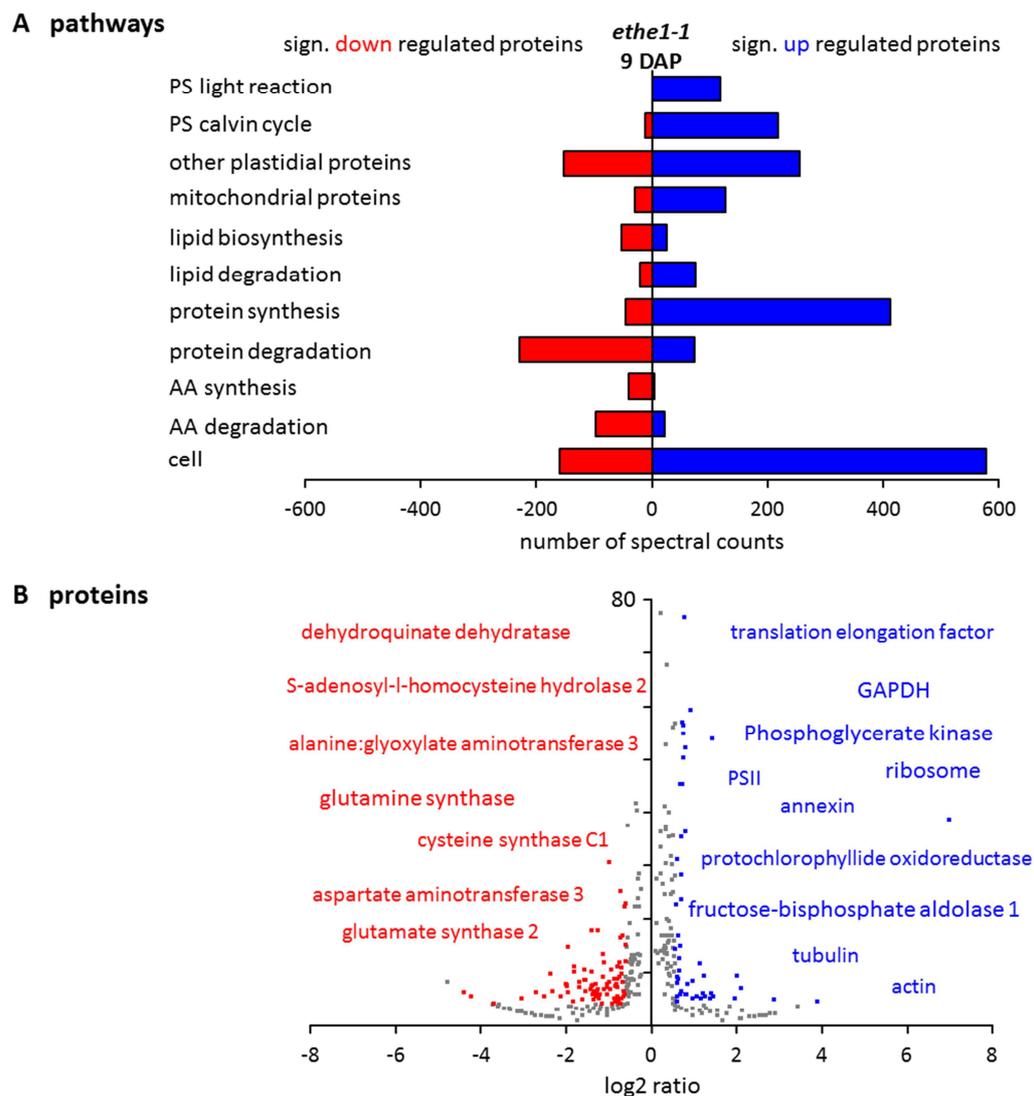

**Figure 4: Metabolite profiles.** Metabolites (sugar metabolites, TCA cycle intermediates, amino acids) of *ethe1-1* and wildtype seeds (4, 5 and 9 DAP) grown under light and dark conditions were extracted and subsequently analysed by GC-TOF MS. Peak areas of the mass ( $m/z$ ) fragments were normalized to the internal standard (ribitol) and fresh weight of the seed samples. **wtL** wildtype seeds grown under light conditions, **wtD** wildtype seeds grown under conditions dark conditions, **mL** *ethe1-1* seeds grown under light conditions, **mD** *ethe1-1* seeds grown under dark conditions.

**A pathways****B proteins**

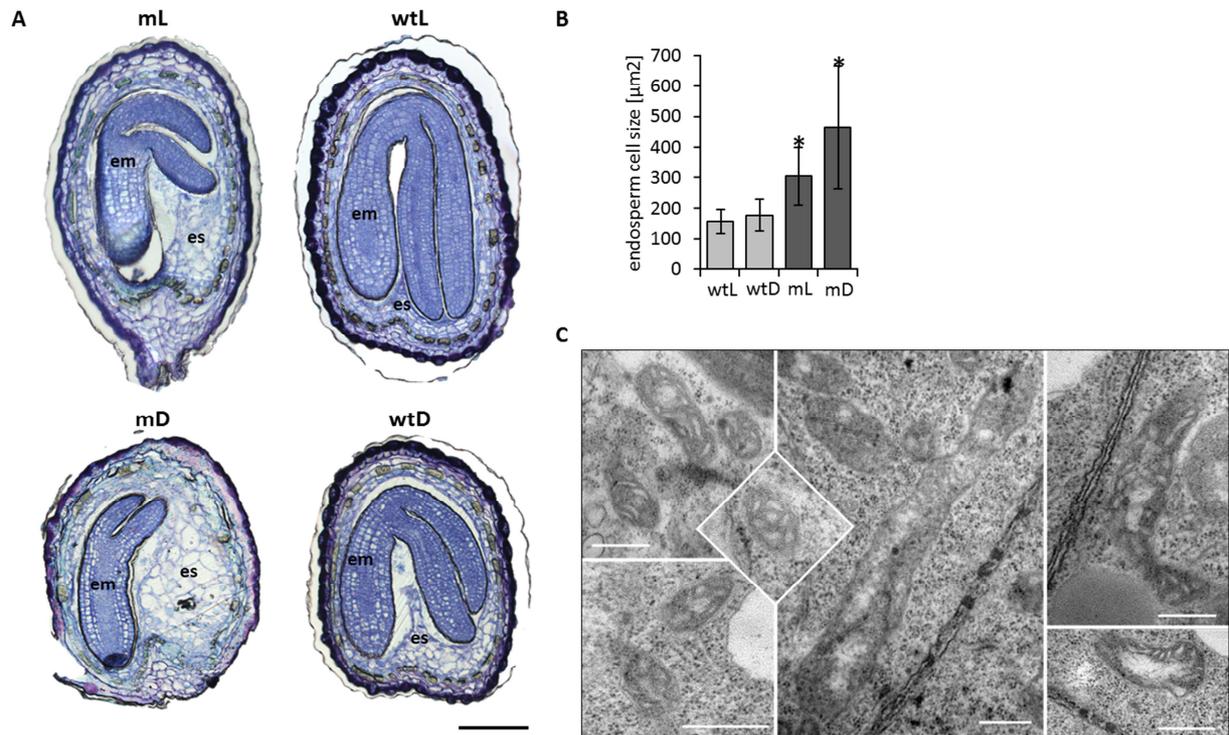

**Figure 5: Regulated pathways and proteins in dark grown seeds.** **A:** Distribution of regulated proteins showing a potentially abundance in dark grown seeds across functional categories, **B:** Significantly regulated proteins in dark grown seeds. **red**= decreased abundance with a ratio  $>1.5$  ( $\log_2 = 0.58$ ) and  $>5$  spectra; **blue** = increased abundance with a ratio  $>1.5$  and  $>5$  spectra, **grey** = significantly abundant proteins with a ratio  $<1.5$  and  $<5$  spectra. Significance levels were calculated with a Student's t-test ( $p$ -value  $\leq 0.05$ ). Differences between the samples are given in  $\log_2$  ratios.

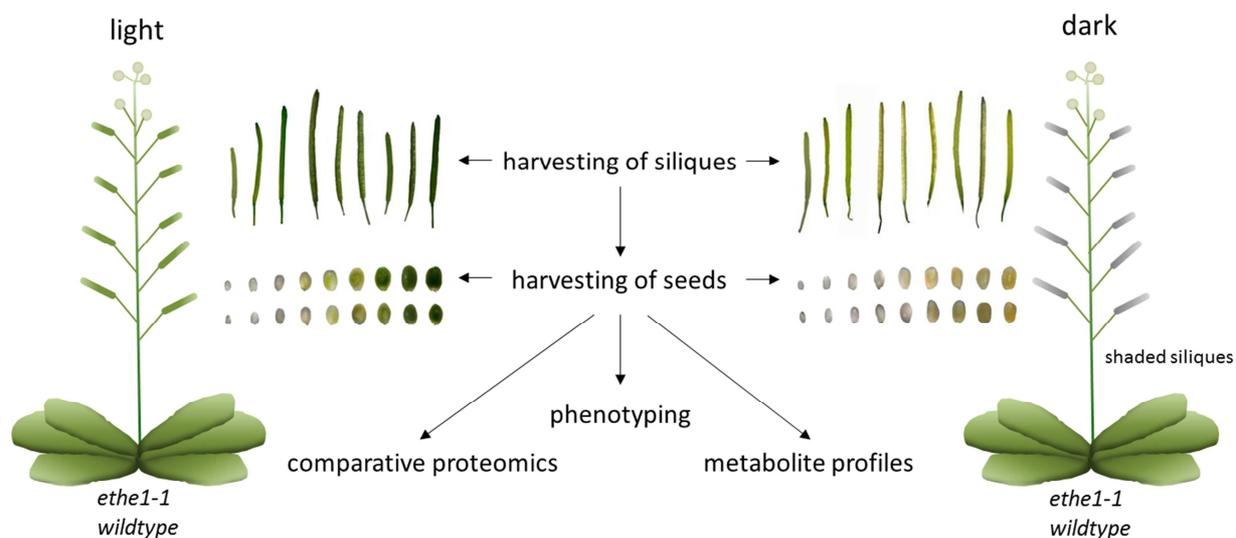

**Figure 6: Regulated pathways and proteins in *ethe1-1* seeds at 5 DAP compared to wildtype. A:** Distribution of regulated proteins showing a potentially abundance in *ethe1-1* seeds at 5 DAP across functional categories, **B:** Significantly regulated proteins in *ethe1-1* seeds. **red**= decreased abundance with a ratio  $>1.5$  ( $\log_2 = 0.58$ ) and  $>5$  spectra; **blue** = increased abundance with a ratio  $>1.5$  and  $>5$  spectra, **grey** = significantly abundant proteins with a ratio  $<1.5$  and  $<5$  spectra. Significance levels were calculated with a Student's t-test ( $p$ -value  $\leq 0.05$ ). Differences between the samples are given in  $\log_2$  ratios.

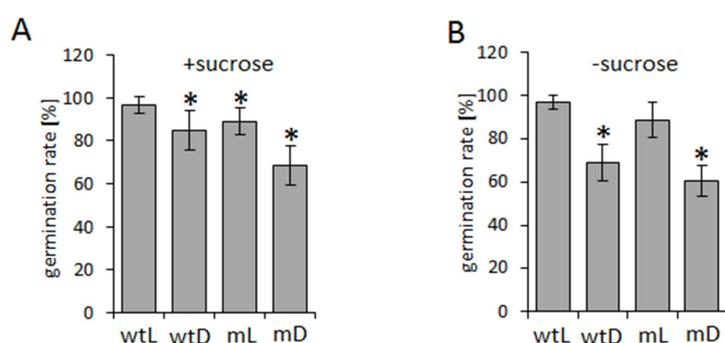

**Figure 7: Regulated pathways and proteins in *ethe1-1* seeds at 9 DAP compared to wildtype. A:** Distribution of regulated proteins showing a potentially abundance in *ethe1-1* seeds at 9 DAP across functional categories, **B:** Significantly regulated proteins in *ethe1-1* seeds. **red**= decreased abundance with a ratio >1.5 ( $\log_2 = 0.58$ ) and >5 spectra; **blue** = increased abundance with a ratio >1.5 and >5 spectra, **grey** = significantly abundant proteins with a ratio <1.5 and <5 spectra. Significance levels were calculated with a Student's t-test ( $p$ -value  $\leq 0.05$ ). Differences between the samples are given in  $\log_2$  ratios.

**Figure 8: Endosperm cellularization and mitochondria structure. A:** Seed sections (7DAP) of wildtype and *ethe1-1* seeds grown under light and dark conditions. Sections were stained with Toluidine Blue O to visualize endosperm cellularization, bars = 100  $\mu\text{m}$  **B:** Endosperm cell size of ca. 50 cells is given as area [ $\mu\text{m}^2$ ] obtained from microscopy images using AxioVision software (Version 4.8.1). Asterisks indicate significant changes to wildtype light (wtL) based on a Student's t-test ( $p\text{-value} \leq 0.05$ ) **C:** Electron microscopic analysis of mitochondrial structure from *ethe1-1* seeds compared to wildtype bars = 500 nm. **wtL** wildtype seeds grown under light conditions, **wtD** wildtype seeds grown under conditions dark conditions, **mL** *ethe1-1* seeds grown under light conditions, **mD** *ethe1-1* seeds grown under dark conditions.

**Supplementary figure 1: Experimental design.** *A. thaliana* wildtype (ecotype Columbia) and *ethe1-1* plants were grown in a climate chamber under longday conditions (16h light/8h dark, 22°C, 85  $\mu\text{mol s}^{-1} \text{m}^{-2}$  light intensity and 65% humidity). Flowers were labeled at the day of pollination. Subsequently siliques were harvested from 1 to 9 DAP. For dark treatment, siliques were shaded with aluminium foil 24 hours after flower tagging while the rest of the plant and control siliques were grown under normal light conditions. Seeds were investigated by phenotyping, comparative proteomics and measuring metabolite profiles.

**Supplementary figure 2: Germination rates.** Sterilized seeds of wildtype and *ethe1-1* grown under light and dark conditions were sown per plate (3 replicates per sample) on MS-medium [60mM sucrose, 1% Agar, 0.5% MS-medium (Duchefa), pH 5.7-5.8 with KOH] and MS medium without sucrose and incubated for another 2 days at 4°C in the dark. Afterwards the plates were placed to a growth chamber (24°C, 16 h light/8 h dark). After 72h germinated seeds were counted. A seed is considered to be germinated when the radicle ruptures the endosperm and the testa.

## Curriculum Vitae

---

Name: Christin Lorenz (née Haase)  
Date of Birth: 12.01.1987  
Place of Birth: Schwerin, Germany  
Citizenship: Citizen of Germany

---

### SCHOOL EDUCATION

1993 - 1997 Primary school in Plate  
1997 - 2006 Secondary school 'Gymnasium am Sonnenberg' in Crivitz  
Qualification: 'Abitur'

---

### ACADEMIC EDUCATION

Oct. 2006 - Sept. 2009 Student at the Leibniz Universität Hannover,  
B. Sc. Plant Biotechnology (grade: "good")  
Thesis: „Proteomische Charakterisierung der Samenentwicklung von  
*Brassica napus*“

Oct. 2009 - Dec. 2012 Student at the Leibniz Universität Hannover,  
M. Sc. Plant Biotechnology (Grade: "with honors")  
Thesis: „Proteomische Charakterisierung des Endosperms von  
*Brassica napus* Samen“

Since Feb. 2012 PhD student at the Leibniz Universität Hannover, Institute of  
Plant Genetics, Department of Plant Proteomics, Prof. Dr.  
Hans-Peter Braun

---

### **26. Tagung Molekularbiologie der Pflanzen in Dabringhausen, Germany (February 2013)**

Poster: “The native structure and composition of the Cruciferin complex in *Brassica napus*”

### **1<sup>st</sup> INNPO World Congress on Plant Proteomics in Hamburg, Germany (June 2014)**

Poster “Metabolism and signaling in a dead end tissue *Brassica napus* seed endosperm”

### **8<sup>th</sup> European Summer School Advanced Proteomics in Brixen, Italy (September 2014)**

Poster: “Metabolism and signaling in a dead end tissue *Brassica napus* seed endosperm”

### **Proteomic Forum in Berlin, Germany (March 2015)**

Poster: “Physiological role of ETHE1 for *A. thaliana* seed metabolism”

## Danksagung

Lieber **Hans-Peter**, an dieser Stelle möchte ich mich als erstes bei Dir dafür bedanken, dass Du mir die Möglichkeit gegeben hast in Deiner Abteilung zu promovieren. Vielen Dank für die großartige Betreuung und Unterstützung während der gesamten Zeit in Deiner Arbeitsgruppe. Sieben einzigartige Jahre, in denen ich eine Menge über die Pflanzenforschung und Proteomik gelernt habe. Vielen Dank, dass Du mich auf diesem Weg begleitet hast. Ich möchte Dir weiterhin danken, dass Du es mir ermöglicht hast nationale und internationale Konferenzen zu besuchen. Es hat mir viel Freude gemacht meine Forschung mit anderen Wissenschaftlern zu diskutieren.

Vielen Dank **Prof. Schmitz**, das Sie sich als Korreferent dieser Dissertation zur Verfügung gestellt haben.

Der gesamten **AG Pflanzenproteomik** möchte ich ganz herzlich für die schöne Zeit danken. Danke für den freundlichen Umgang miteinander und eure Hilfsbereitschaft!

Liebe **Dagmar**, ich danke Dir dafür, dass Du mir schon im Bachelor-Studium das 1x1 der Proteomik beigebracht hast und mir bei Problemen oder Fragen jederzeit geholfen hast.

Ich möchte mich ganz herzlich bei **Stephanie Sunderhaus** für die Betreuung und Unterstützung am Anfang meiner Doktorarbeit danken.

Ein ganz besonderer Dank gilt **Tatjana**. Danke, dass ich gemeinsam mit Dir arbeiten durfte. Es hat mir sehr viel Freude gemacht. Ich habe wahnsinnig viel gelernt und Du hast mich mit der Begeisterung für Dein Thema infiziert. Danke ganz besonders für die große Unterstützung beim Fertigstellen der Manuskripte in den letzten Wochen!

Lieber **Holger**, ich danke Dir für Deinen unermüdlichen Einsatz im Labor, besonders wenn das Massenspektrometer mal wieder Schwierigkeiten gemacht hat. Ich möchte Dir danken, dass Deine grüne Bürotür jederzeit für mich offen stand und Du auch im größten Chaos immer Zeit gefunden hast, mich zu unterstützen.

Lieber **Hardy**, liebe **Ljudmilla**, vielen Dank für eure Unterstützung bei meinen Projekten als Experten der Samenbiologie. Es hat mir immer viel Freude gemacht, mit euch über meine neusten Ergebnisse zu diskutieren.

Bei meinen lieben Bürokolleginnen **Beate** und **Christine** möchte ich mich für die schöne Zeit in unserem „Wohnzimmer“ bedanken. Es war eben nicht nur ein Büro, sondern viel mehr. Ich möchte euch danken, dass trotz der vielen Arbeit der Spaß nie zu kurz kam. Ich werde euch sehr vermissen...**007** die Lizenz zum Forschen.

Liebe **Jenni**, vielen Dank, dass Du zu jeder Zeit für mich da warst und immer ein offenes Ohr für mich hattest.

Lieber **Michael**, ohne Deine kompetente Hilfe in allen Softwarefragen, wäre ich wohl heute noch nicht mit meiner Doktorarbeit fertig, sondern würde immer noch versuchen meine Massenspektrometrie-Daten per Hand auszuwerten. Vielen Dank für Deine Unterstützung.

Ich möchte **Tjorven** danken, die mit viel Einsatz und Ausdauer Samen präpariert hat und mich im Labor unterstützt hat.

Liebe **Edda**, danke für Deinen Einsatz und Deine Unterstützung während meiner Zeit in dieser Abteilung. Ich danke Dir weiterhin für die vielen wunderbaren Gespräche.

Vielen Dank and **Herrn Geyer** und **Herrn Barth**, die immer dafür gesorgt haben, dass es meinen Versuchspflanzen gut geht!

Ich möchte meiner **Familie** danken, die immer hinter mir steht und mich bei Allem unterstützt. Auch wenn es manchmal schwierig war, wart ihr jederzeit für mich da. Ich danke Euch für Eure Liebe.

Lieber **Bastian**, danke dass es Dich gibt!
